SOFTWARE DESIGN DESCRIPTION

Contents

1.0 INTRODUCTION

This report describes the mathematical formulations and implementation structure for version 2 of the GENII software product (GENII-V2). The following sections define the purpose and scope of this report, the framework operating structure for GENII-V2, and definitions and acronyms used in this report.

1.1 PURPOSE

The purpose of this document is to describe the architectural design for the GENII-V2 software package. This document defines details of the overall structure of the software, the major software components, their data file interfaces, and specific mathematical models to be used. The design represents a translation of the requirements (Napier et al. 1995) into a description of the software structure, software components, interfaces, and necessary data. The design focuses on the major components and data communication links that are key to the implementation of the software within the operating framework.

The intended audience for this design report is the PNNL software development team, independent reviewers, testing team, users, and project and line management who need a thorough understanding of the software capabilities.

1.2 SCOPE

The GENII-V2 software package has been developed for the Environmental Protection Agency, Office of Radiation and Indoor Air.

The software has two distinct user groups:

1)   staff of EPA who will use the software frequently to perform analyses,

2)   a large group of occasional users who may be required to perform analyses with the software.

All users are assumed to be competent in the areas of health physics and environmental analysis, with some basic familiarity with use of computers.

The purpose of the GENII-V2 software package is to provide the capability to perform dose and risk assessments of environmental releases of radionuclides. The software also has the capability of calculating environmental accumulation and radiation doses from surface water, groundwater, and soil (buried waste) media when an input concentration of radionuclide in these media is provided. This report represents a detailed description of the capabilities of the software product with exact specifications of mathematical models that form the basis for the software implementation and testing efforts.

This report also presents a detailed description of the overall structure of the software package, details of main components (implemented in the current phase of work), details of data communication files, and content of basic output reports.

1.3 FRAMEWORK OPERATING STRUCTURE

The components of GENII-V2 have been developed to operate within the Framework for Risk Analysis in Multimedia Environmental Systems (FRAMES). An overview of this software concept is provided by Whelan et al. (1997). FRAMES is an open-architecture, object-oriented system that allows the user to choose the most appropriate models to solve a particular simulation problem. The components of GENII-V2 are implemented through FRAMES by meeting requirements for data input and output file specifications defined for FRAMES. Details of FRAMES and implementation of the GENII-V2 components is described in Section 2.

1.4 DEFINITIONS AND ACRONYMS

Definition of terms, acronyms, and abbreviations used in this report are defined below. Many of the technical term definitions are based on definitions provided in the glossary of Kennedy and Strenge (1992).

Absorbed dose - The energy imparted by ionizing radiation per unit mass of irradiated material. The units of absorbed dose are the rad and the gray (Gy).

Activity - The rate of disintegration (transformation) or decay of radioactive material. The units of activity are the curie (Ci) and the becquerel (Bq).

Acute release - the release of material to the air or surface water over a brief period, assumed in the models to be on the order of a few hours.

ASCII - American Standard Code for Information Interchange, a set of codes used in data communications.

Bq - Abbreviation for becquerel, a unit of activity.

Chronic release - a release of material to the air or surface water that continues essentially uniformly over a long period, taken in the models to be a year.

Ci - Abbreviation for curie, a unit of activity.

Class (or "lung class" or "inhalation class") - A classification scheme for inhaled material according to its rate of clearance form the pulmonary region of the lung. Materials are classified as F, M, or S (previously D, W, or Y), and apply to a range of clearance half-times for F (Fast) of less that 10 days, for M (Medium) from 10 to 100 days, and for S (Slow) of greater than 100 days.

Collective dose - The sum of the individual doses received in a given period of time by a specified population from exposure to a specified source of radiation.

Committed dose equivalent ($H_{T,50}$) - The equivalent dose to organs or tissues of reference (T) that will be received from an intake of radioactive material by an individual during the 50-year period following the intake.

GENII - Acronym for the "GENeration II" computer programs developed at Hanford (Napier et al. 1988). Includes by implication the GENII-S stochastic version prepared at Sandia National Laboratories (Leigh et al. 1992).

GENII-V2 - Acronym for the version 2 of GENII developed for the EPA and documented in this report.

ICRP - International Commission on Radiological Protection

Internal dose - That portion of the equivalent dose received from radioactive material taken into the body.

JFD - Acronym for Joint Frequency Data; information on the joint probability of occurrence of windspeed, direction, and atmospheric stability class.

Member of the public - An individual in an uncontrolled or unrestricted area. However, an individual is not a member of the public during any period in which the individual receives an occupational dose.

Pathway - The potential routes through which people may be exposed to radiation or radioactive materials. Typical radiation exposure pathways include external exposure to penetrating radiation, inhalation of airborne materials, and ingestion of materials contained in surface contamination, food products, or drinking water.

Public dose - The dose received by a member of the public from exposure to radiation and to radioactive materials in unrestricted areas. It does not include occupational dose, or dose received from natural background, as a patient from medical practices, or from voluntary participation in medical research programs.

Rad - The special unit of absorbed dose. One rad is equal to an absorbed dose of 100 ergs/g or 0.01 joule/kg (0.01 gray).

Radiation (ionizing radiation) - Alpha particles, beta particles, gamma rays, x-rays, neutrons, high-speed electrons, high-speed photons, and other particles capable of producing ions. Radiation, as used here, does not include non-ionizing radiation, such as sound, radio, or microwaves, or visible, infrared, or ultraviolet light.

Reference man - A hypothetical aggregation of human physical and physiological characteristics arrived at by international consensus. These characteristics may be used by researchers and public health workers to standardize results of experiments and to relate biological insult to a common base.

Rem - The special unit of equivalent dose. The equivalent dose in rem is equal to the absorbed dose in rad multiplied by the quality factor (1 rem = 0.01 Sv).

Risk conversion factor - a precalculated multiplier that translates activity ingested or inhaled into expected likelihood of effect.

Scenario - A combination of radiation exposure pathways used to model conceptually the potential conditions, events, and processes that result in radiation exposure to individuals or groups of people.

Sievert - The SI unit of equivalent dose. The equivalent dose in sieverts is equal to the absorbed dose in grays multiplied by the quality factor (1 Sv = 100 rem).

Software - A sequence of computer-readable instructions suitable for processing by a computer. Same as program and code.

Software Requirement Specification (SRS) - Documentation of the essential requirements (functions, performances, design constraints, and attributes) of the software and its external interfaces (ANSI/IEEE Standard 730-1983).

STAR - Acronym for Stability Array; a standard available format for meteorological summary data.

Sv - Abbreviation for sievert.

Weighting factor, w_T, for an organ or tissue (T) - The proportion of the risk of stochastic effects resulting from irradiation of that organ or tissue to the total risk of stochastic effects when the whole body is irradiated uniformly.

2.0 SOFTWARE STRUCTURE

This section describes the overall structure of the FRAMES and GENII-V2 software packages and provides general information on the purpose and content of the various components.

The controlling component is the FRAMES software package. This package has a framework user interface (FUI) that serves as the primary interface with the user. The FUI allows the user to select specific calculational components to be included in the analysis, select radionuclides, view intermediate and result files, prepare result charts, and perform uncertainty and sensitivity analyses. The framework allows the user to select specific components to be included in an analysis. The general component analyses available under FRAMES are as follows:

Contaminant Database
Source Term Definition/Estimation
Vadose Zone Transport
Aquifer Transport
Surface Water Transport
Overland Transport
Atmospheric Transport
Exposure Pathways
Receptor Intake
Health Impact Estimation
Sensitivity Analysis
Report Generation

These components represent the building blocks of an analysis from which the user selects in developing a case for analysis. The calculational software for each of these components is not part of the FRAMES software package. In order to be able to perform an analysis, the user must have available calculational software for the components to be included. The original GENII program (Napier et al. 1988) has been revised to be represented by calculational components that can be exercised under the control of FRAMES. The GENII-V2 software package provides calculational software for the following components:

Source Term Definition
Atmospheric Transport
Surface Water Transport
Exposure Pathways
Receptor Intake
Health Impact Estimation
Selected report generation

The GENII-V2 software package does not include calculational software for vadose zone, overland transport, or aquifers. However, if the user has software for these calculations available (designed to meet the requirements of the FRAMES operating system), then these components can be coupled to the GENII-V2 calculational components and included in the analysis.

To perform an analysis, the user selects the components to be included in an analysis, provides necessary input data (via the user interfaces), and runs each component. Some of these components may be applied one or more times in an analysis. For example, the environmental transport via groundwater may actually be represented by a source unit, one or more unsaturated (vadose) zones, and a saturated zone (aquifer) with calculational components selected for each.

The FUI allows the user to setup an analysis and specify the calculational components to be used. The FRAMES software package also has a chemical and radionuclide database, an sensitivity/uncertainty manager (SUM[3], sensitivity/uncertainty module for multimedia models), help information, global input data (GID) file, and file specifications for primary data communication files (PDCFs). Summary descriptions of each of these components/files follow. The components and communication links are indicated schematically in Figure 2.1. This figure shows the primary screen for the framework user interface with example modules to illustrate the possible connections. Primary communication data files are indicated showing their use to transfer information between specific modules.

2.1 FRAMEWORK USER INTERFACE

The framework user interface (FUI) controls the overall interface with the user and execution of specific components. A series of well-ordered screens is used to step the user through the process of problem definition and selection of options for setting up the analysis. As may be required for each of the selected options, the FUI activates other user interfaces to control input of parameters for user selected GENII-V2 calculational components. The control of input for each component is performed by module user interface (MUI) programs. The MUI's are specific to the software package (e.g., GENII-V2) and have capabilities defined by the developers of the specific package. The GENII-V2 components all have help files defining the parameters pertinent to the specific component.

2.2 PRIMARY DATA COMMUNICATION FILES (PDCFS)

The Primary Data Communication Files are basic files for transferring information between specific calculational components. Files of this type included under FRAMES are:

File Content	Extension
Soil concentration	SCF
Flux to air	AFF
Flux to surface water	WFF
Air transport output	ATO
Water concentration	WCF
Exposure pathway media concentrations	EPF

Receptor Intake	RIF
Health Impacts	HIF
Sensitivity analysis inputs	SIF

Figure 2.1 illustrates use of each of these files as communication links between specific modules. The content and format of these files is defined by the requirements of the FRAMES software package. The calculational components must read and write information consistent with these defined requirements. The user cannot modify PDCF content or format. Definition of the PDCF file content and format has been based on careful consideration of purpose and capabilities of each component. The specifications for the PDCF files are given in Appendix A.

The purpose of the PDCFs can be thought of as following the activity of the radionuclides from the source, through the environment to the exposed individual or population, and then through evaluation of the risk from exposure. The PDCFs, therefore, contain information related to the radionuclides and their amounts in various media along the path of the analysis. The PDCFs will typically not contain parameter values that are specific to a few mathematical models, but not to all models. The PDCFs are generated by the calculational components to provide information to subsequent components. The PDCFs can be generated by calculational components or supplied by users external to components available under the framework user interface.

Figure 2.1. The primary FRAMES interface screen showing GENII icons and file types
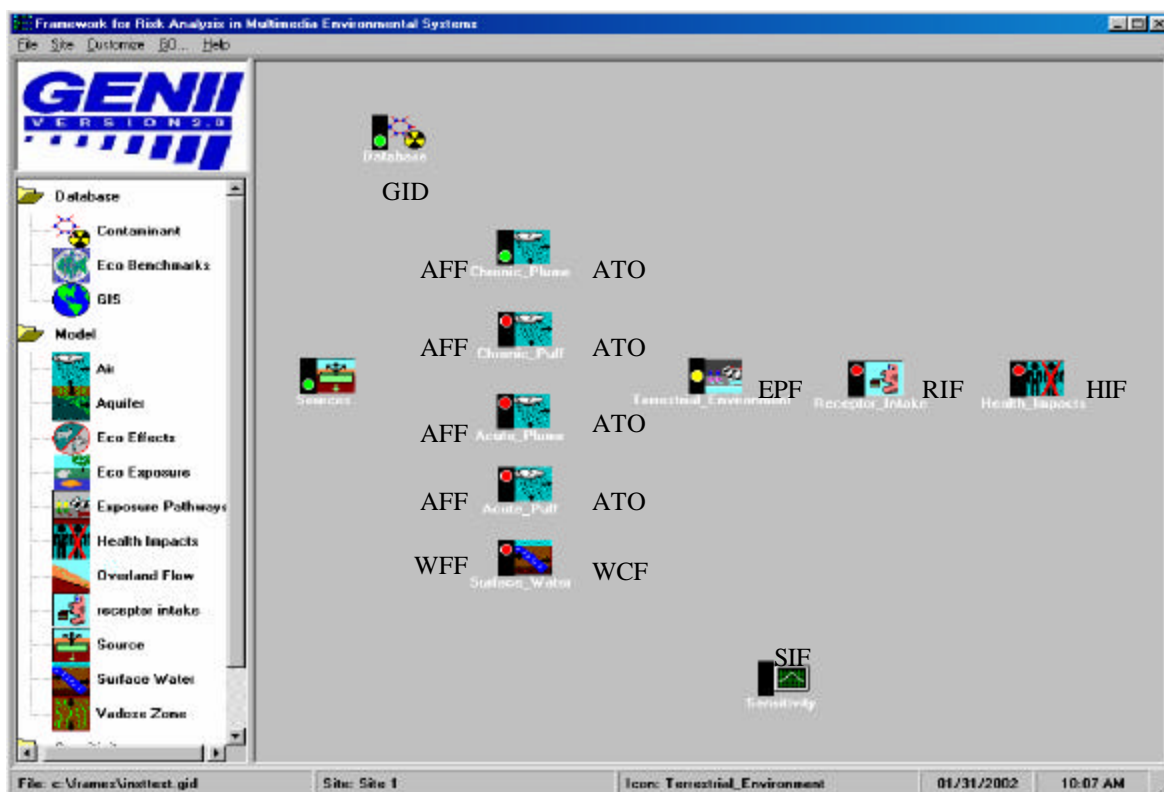

2.3 SENSITIVITY USER INTERFACE

The performance of uncertainty and sensitivity studies requires a sensitivity user interface to control selection/specification of the scope of the analysis, and to cause repetitive implementation of the selected components. FRAMES provides a sensitivity/uncertainty user interface (SUI) and calculational program (SUM^3) that can be used within the operating concept of FRAMES. The GENII-V2 software components are compatible with SUI/SUM^3 operation.   The SUI also controls analysis of the output results and handling of the potentially large amount of output data.

A sensitivity/uncertainty analysis is performed by selecting the software components to be included in the case and providing input parameters for all components. The SUI is then activated. The user is then allowed to select parameters (from the software components included in the analysis) and to define probability distributions for these parameters. The user also indicates which output parameters (e.g. water concentration, cancer incidence) are to be saved for subsequent statistical analyses. The SUI then starts SUM^3 to perform the repetitive calculations for the number of sample runs defined by the user. Results are saved for review. Connections are provided for simple analysis and graphical presentation using EXCEL.

2.4 GENII-V2 CALCULATIONAL MODULES

The calculational modules provide the user with ability to evaluate specific components of the analysis. The GENII-V2 software package contains calculational modules for the following components.

Source Term Definition
Surface Water Transport
Atmospheric Transport
Exposure Pathways
Receptor Intake
Health Impact Estimation

Summaries of each of these calculational components follow.

2.4.1 GENII-V2 Source Term Definition Module

The radionuclide source term is defined using the source term module provided with the GENII-V2 software package. This module allows the user to define the initial soil concentration (for the near-field exposure module), release rates to the atmosphere (for the atmospheric transport modules), and release rates to surface water (for the surface water module). The output from the source term module is written to primary data communication file (PDCFs) as follows: to the soil concentration file (SCF) for coupling to the near-field exposure module; to the air flux file (AFF) for coupling to the atmospheric transport modules; and to the water flux file (WFF) for coupling to the surface water transport module. Parameters defined by the user through the source term

module user interface are also saved in the global input data file in a section for the source term module. No auxiliary input or output files are used or generated by the source term module.

2.4.2 GENII-V2 Surface Water Transport Module

Radionuclide transport in surface water is evaluated using the GENII-V2 surface water transport module. This module allows the user to define characteristics of the surface water body, and the location of the usage location at which individual may be exposed. The time-variant release rates are read from the water flux file (WFF) and results of the calculation are written to the water concentration file (WCF). The WCF contains the average water concentration over the defined release period at the exposure location. Parameters defined by the user through the surface water transport user interface are also saved in the global input data file in a section for the surface water transport module. No auxiliary input or output files are used or generated by the surface water transport module.

2.4.3 GENII-V2 Atmospheric Transport Modules

The GENII-V2 software package contains four calculational programs for the atmospheric transport component. There are puff- and plume-based programs for both acute and chronic releases. The suite of codes accounts for the transport, diffusion, deposition, depletion, and decay of radionuclides while in the atmosphere. Input to the models is the air release rate supplied in the air flux file (AFF), and output is to the air transport output (ATO) file. Additional input of meteorological data is through an auxiliary data file.

The acute plume module employs the straight-line Gaussian plume model with concentration variation in the lateral and vertical directions (sometimes referred to as the bi-variate plume model). The chronic plume module uses the sector-averaged straight-line Gaussian plume model. The Lagrangian puff model is used for the acute and chronic puff modules. The Lagrangian puff model consists of two parts: a wind field model (to move the puffs) and a diffusion model (to describe the spread of the puffs). The mathematical formulations for these four modules are provided in Section 5.0.

2.4.4 GENII-V2 Exposure Pathways Modules

Three exposure pathway modules are provided in the GENII-V2 software package. The near-field module allows estimation of exposures to individual in proximity to a contaminated soil source area. The acute exposure component allows evaluation of exposures over a short time period (hours to days) from acute airborne or waterborne releases. The chronic exposure component allows evaluation of exposure from routine releases to air or water. Each of these exposure components is summarized in the following sections.

2.4.4.1 <u>GENII-V2 Near-field Exposure Module</u>

The near-field exposure module may be used to simulate exposure scenarios where the exposed individual comes in direct contact with (e.g., lives on) the contaminated source. This source may be represented as a contaminated surface layer, a buried layer of waste (deep soil), or a package of buried waste. These compartments are represented by a three-compartment soil model to simulate transfer and loss of radioactive contaminants over time. The user may define initial contamination in one or more of the three compartments. Exposure pathways linked to the near-field model are those associated with contact with soil, suspension of surface soil, and agricultural pathways resulting from crop production in the contaminated layers (surface or deep soil).

Input to the near-field module is initial soil concentration (surface soil or deep soil), and/or the initial total activity in the waste package. These values are read from the soil concentration file (SCF). Output from the module is the average exposure media concentrations for each exposure pathway, averaged over the user-defined exposure duration, and written to the exposure pathway file (EPF). The mathematical formulations for the near-field exposure module are provided in Section 7.0.

2.4.4.1 <u>GENII-V2 Acute Exposure Module</u>

The acute exposure model is used to evaluate exposures following accidental or short-term releases with transport to an exposure location. Transport may be via the atmosphere or surface water: groundwater transport is not considered for acute releases because of the long time periods generally required for transport of contaminants through aquifers. Exposure pathways linked to the acute exposure model are those associated with air exposure (inhalation and external exposure), contact with soil following atmospheric deposition or surface water deposition (irrigation), resuspension of surface soil, agricultural pathways contaminated by airborne or irrigation water deposition, domestic water use (drinking and showering), and recreational water pathways (swimming, boating, and shoreline activities). Exposure to agricultural products is evaluated assuming the deposition to occur at the time of crop harvest.

The input to the acute transport module is read from air concentration files (ATO), or water concentration files (WCF). Output from the module is the average exposure media concentration for each exposure pathway, averaged over the user-defined exposure duration, and written to the exposure pathway file (EPF). The mathematical formulations for the acute exposure module are provided in Section 8.0.

2.4.4.1 <u>GENII-V2 Chronic Exposure Module</u>

The chronic exposure model is used to evaluate exposures over extended periods of media contamination. Transport may be via the atmosphere, surface water, or groundwater media. Exposure pathways linked to the chronic exposure model are those associated with air exposure (inhalation and external exposure), contact with soil

following atmospheric deposition or water deposition (irrigation), resuspension of surface soil, agricultural pathways contaminated by airborne or irrigation water deposition, domestic water use (drinking and showering), and recreational water pathways (swimming, boating, and shoreline activities). Exposure to agricultural products is evaluated assuming the deposition occurs uniformly over annual periods, with deposition rates defined as a function of time from atmospheric concentration files (ATO) or waterborne concentration files (WCF).

The input to the chronic transport module is read from air concentration files (ATO), or water concentration files (WCF). Output from the module is the annual average exposure media concentration for each exposure pathway for the user-defined exposure duration, and written to the exposure pathway file (EPF). The mathematical formulations for the chronic exposure module are provided in Section 9.0.

2.4.5 GENII-V2 Receptor Intake Module

The receptor intake module uses the exposure media concentration values from the exposure pathway module to estimate the intake by the exposed individual(s). The intake is represented as the total activity taken in (via inhalation or ingestion). For external exposure pathways, the result is expressed as the average concentration in the exposure media over the exposure duration, corrected for any appropriate modification factors (e.g., occupancy fraction by the exposed individual). Several user-defined age groups may be used. Results of the analysis are written to the receptor intake file (RIF). The mathematical formulations for the receptor intake module are provided in Section 10.0.

2.4.6 GENIIV2 Health Impact Module

The health impacts from the receptor intake module are converted to estimates of radiation or health impacts by the health impacts module. The user may choose the method for evaluation of health impacts and the endpoint of interest (e.g. radiation dose, cancer incidence, cancer fatality, etc). Results may be calculated and reported by organ or cancer site. Output from this module is written to the health impacts file (HIF). The mathematical formulations for the health impacts module are provided in Section 11.0.

2.5 GLOBAL INPUT DATA FILE

The global input data file (GID) contains values for all parameters required by FRAMES, and for each component selected by the user to be included in the analysis. The parameters for FRAMES are automatically added to the GID as the user defines the scope of the analysis and selects contaminants to be considered. The parameters for each selected component are added by the user interface for the component. Under normal operating conditions, the user will not need to access or view the GID. The specifications for the GID file are given in Appendix A.

2.6 AUXILIARY DATA INPUT/OUTPUT FILES (ACDFs)

Each calculational component may require special input files and may generate output files that are in additional to the primary data communication files. The definition and use of the auxiliary files is up to the software developer.

The ACDFs are typically component specific and will vary between calculational components for a specific analysis. For example, if three calculational components are available for estimation of chronic atmospheric transport, it is likely that each of the components will require ADFs with different content and structure. However, all three of the components must be capable of generating output in the same form defined for the PDCFs for the next component (chronic terrestrial and aquatic transfer and accumulation module).

Examples of ACDFs used in the GENII-V2 components are atmospheric data files used by the various atmospheric transport models, and dose rate and risk conversion factors used in the calculation of impact. More information on GENII-V2 specific ACDFs is provided in Section 3.

2.7 REFERENCE FOR SECTION 2

Napier, B. A, R. A. Peloquin, D. L. Strenge, and J. V. Ramsdell. 1988. *HANFORD ENVIRONMENTAL DOSIMETRY UPGRADE PROJECT. GENII - The Hanford Environmental Radiation Dosimetry Software System. Volume 1: Conceptual Representation, Volume 2: Users' Manual, Volume 3: Code Maintenance Manual*. PNL-6584, Vols. 1-3, Pacific Northwest Laboratory, Richland, Washington.

3.0 AUXILIARY DATA COMMUNICATION FILES (ADCFs)

The auxiliary data communication files (ADCFs) contain input parameter values for specific components. The format and content of the ADCFs are defined by the developer of the specific component and include information necessary to exercise the models of the component. ADCFs defined for GENII-V2 are described in this section. The use of ADCFs has been minimized by placing as much data as possible into the global input data file (GID). This is desirable because the GID is intended to contain all data necessary to perform an analysis.

3.1 AUXILIARY DATA COMMUNICATION FILE SUMMARIES

The ADCFs necessary for the components implemented in GENII-V2 are summarized in Table 3.1. Summaries of each ACDF are given in the following sections, with detailed file descriptions given in Appendix B.

3.2 RADIONUCLIDE MASTER DATA FILE

The radionuclide master data library (RMDLIB.DAT) contains all radiological decay data in addition to the specification of all radionuclides for which data is included in the GENII-V2 software system. The radionuclides are organized into decay chains ordered by atomic number under the radionuclides highest in the chain. The data in this file are used by the chain decay processor to account for radioactive decay and progeny ingrowth with time. RMDLIB.DAT currently contains information on 245 explicit radionuclides. Decay of a number of very short-lived radionuclides within the decay chains of longer-lived radionuclides is also considered. The criteria for inclusion in RMDLIB.DAT as an explicitly considered chain member include a half-life greater than 10 minutes.

The file is provided with the software package and is not intended to be modified. However, a knowledgeable user should be able to modify the file (to add, delete, or change decay chain representation) using an ASCII file editor. The content and structure of the file is described in Appendix B.

3.3 METEOROLOGICAL DATA

Because of the specialized nature of this input data, the file formats are discussed separately in Appendix B of the GENII-V2 Users' Guide. Automated utility codes are provided to take meteorological data from several common sources and put it into the necessary format for GENII-V2 input.

Appendix B to the GENII Users' Guide describes the use of hourly and joint frequency data in multiple formats, and the structure of the library of air submersion dose coefficients (cloud shine doses) CSHNLIB.DAT.

Table 3.1 Summary of ADCFs for GENII-V2

File Description	Components using file
Radionuclide master data - RMDLIB.DAT	Atmospheric Transport Surface Water Transport Exposure Pathways Receptor Intake Health Impacts
Meteorological data – Site specific hourly data Site specific joint frequency data Air submersion dose rate data	Atmospheric transport
Radiation factor index file – FGR13PAK.NDX	Health Impacts
Radiation External dose rate factors Air submersion - F12TIII1.EXT Water immersion - FGR12F32.DAT Soil surface - F12TIII3.EXT Soil volume - F12TIII7.EXT	Health Impacts
Radiation internal dose rate factors Inhalation – FGR13INH.HDB Ingestion – FGR13ING.GDB	Health Impacts
Radiation exposure risk factors Inhalation - FGR13INH.RBS Ingestion - FGR13ING.RBS External – FGR13EXT.RBS	Health Impacts

3.3 DOSIMETRY/RISK FILES

The GENII-V2 options for calculating radiation dose are quite complex, and a large amount of radionuclide/pathway/age specific data is required. Because the calculation of dose and risk using ICRP Publication 26 and 30 (ICRP 1979 - 1982), calculation of risk using EPA slope factors (EPA 1997), and calculation of dose and risk using ICRP Publication 60 and 72 (ICRP 1990; ICRP 1997) and Federal Guidance Report 13 (Eckerman et al.1998) factors are essentially redundant, much of the data are required in separate formats. The calculation capabilities for the ICRP26/30 and EPA slope factor methods are derived from parallel capabilities in the MEPAS code system (Whelan et al. 1992), and so the data are available within the FRAMES system. The ICRP-60 and Federal Guidance Report 13 methods are derived from methods developed for EPA at Oak Ridge National Laboratory, and use that file structure.

3.3.1 Radiation Dose Factor Index File

The dose and risk factors provided with the GENII-V2 system were developed at Oak Ridge National Laboratory for Federal Guidance Report 13 (Eckerman et al. 1998). The internal (inhalation and ingestion) age-dependent dose conversion factors are the basis of those found in ICRP Publications 60 through 72. Because the development of the files containing these factors was independent of the RMDLIB.DAT file, the file structure differs from that of the rest of the GENII-V2 files. The file FGR13PAK.NDX allows the GENII-V2 system to have direct access to the dose and risk files. This file has radionuclide identifiers, half-life information, and cross-reference line numbers for the remaining data files.

3.3.2 External Dose Rate Conversion Factor Files

The data files F12TIII1.EXT, F12TIII3.EXT, and F12TIII7.EXT contain factors that relate radionuclide concentrations in air, soil surface, and soil volume, respectively, to dose rate. Each of these files is parallel in structure and size; each radionuclide line number is identified in the index file FGR13PAK.NDX described above. Each of these files provides dose conversion factors for 24 human body organs and tissues.

The data file FGR12F32.DAT is a file parallel in structure to the three taken from Federal Guidance Report 12 but containing external dose rate factors for submersion in contaminated water (a pathway not included in FGR 12). This data set was added to give GENII-V2 the capability of handling these types of exposure, requiring the modification of the file reading software appropriately.

These files are provided with the GENII-V2 software package, and each is used by the health impacts calculational component. Data are provided for more radionuclides than are explicitly listed in RMDLIB.DAT – however, many are considered to be implicit progeny radionuclides within the RMDLIB.DAT structure. The GENII-V2 health risk component accounts for the decay energies of the implicit progeny in the dose rate factor assigned for the explicit parent radionuclides. The content and structure of the files are described in Appendix B.

3.3.3 Internal Dose Conversion Factor Files

The files FGR13ING.GDB and FGR13INH.HDB contain age dependent radiation dose factors for the pathways of ingestion and inhalation. Each of these files is parallel in structure and size; each radionuclide line number is identified in the index file FGR13PAK.NDX described above. Each of these files provides dose conversion factors for 24 human body organs and tissues. The ingestion file further provides information subdivided by the potential GI-tract uptake fraction (f1) for each radionuclide. The inhalation file provides information subdivided by the ICRP lung model retention classes F, M, and S (fast, medium, and slow clearance rates).

These files are provided with the GENII-V2 software package, and each is used by the health impacts calculational component. Data are provided for more radionuclides than are explicitly listed in RMDLIB.DAT – however, many are considered to be implicit progeny radionuclides within the RMDLIB.DAT structure. The GENII-V2 health risk component accounts for the decay energies of the implicit progeny in the dose rate factor assigned for the explicit parent radionuclides.   The content and structure of the files are described in Appendix B.

3.3.4 Risk Conversion Factor Files

The files FGR13ING.RBS and FGR13INH.RBS contain radiation risk conversion factors for the pathways of ingestion and inhalation. Each of these files is parallel in structure and size. The file FGR13EXT.RBS provides similar factors for the external pathways of air submersion, surface soil, and soil volume. Each of these files provides risk conversion factors for 15 potential human cancer sites; each radionuclide line number is identified in the index file FGR13PAK.NDX described above.   The ingestion file further provides information subdivided by the intake pathways of drinking water and food, as described in Federal Guidance Report 13, for each radionuclide. The inhalation file provides information subdivided by the ICRP lung model retention classes F, M, and S (fast, medium, and slow clearance rates).

These files are provided with the GENII-V2 software package, and each is used by the health impacts calculational component. Data are provided for more radionuclides than are explicitly listed in RMDLIB.DAT – however, many are considered to be implicit progeny radionuclides within the RMDLIB.DAT structure. The GENII-V2 health risk component accounts for the decay energies of the implicit progeny in the dose rate factor assigned for the explicit parent radionuclides.   The content and structure of the files are described in Appendix B.

4.0 SENSITIVITY USER INTERFACE

The uncertainty and sensitivity analysis is controlled by the sensitivity user interface (SUI) which provides the capability to perform uncertainty and sensitivity analyses for user specific portions of the environmental analysis process. FRAMES provides SUI software interface and the calculational component Sensitivity/Uncertainty Module for Multimedia Models (SUM^3).

This section describes the purpose and scope of the uncertainty and sensitivity use interface, and describes the mathematical approaches and algorithms used in the stochastic analyses of SUM^3. Section 4.1 describes the interface and structure. Section 4.2 provides: i) the conceptual background for interpreting the statistical algorithms and their use in generating random variables, ii) a description of the efficient Latin hypercube sampling approach to obtaining correlated or uncorrelated random vectors from univariate random variables, and iii) an identification of the univariate statistical distributions available and the algorithms used for random generation. Section 4.3 discusses the methods and algorithms used for uncertainty analysis results. References for this section are given in Section 4.4. A separate description of the application of SUM^3 to the GENII-V2 modules is provided in the GENII-V2 users' guide.

4.1 INTERFACE

The sensitivity user interface allows the user to define the scope of the uncertainty and sensitivity analyses to be performed, activates the calculational component SUM^3 to perform the repetitive calculations, and finally performs the sensitivity analysis of results. For each module included by the user in the specific analysis, the user is allowed to select parameters to be varied in the uncertainty/sensitivity analysis. The parameters available for this analysis are determined by the developers of the specific modules – primarily to prevent stochastic variation of control parameters. A summary of parameters available to the user for each of the GENII-V2 modules is given in Appendix E. The user is allowed to select and define probability distributions for each of the parameters for the sensitivity/uncertainty analysis.   The distributions available to the user are described in the following sections.

4.2 MATHEMATICAL STRATEGIES FOR GENERATING RANDOM VARIABLES

This section presents random-number-generation theory and algorithms for statistical distributions implemented in the SUM^3 module of FRAMES. This module is available for all GENII-V2 modules. The topics addressed are probability concepts, including generation of uniform random numbers, the concepts of stratified and Latin Hypercube sampling (LHS) and algorithms for random-number generation.

4.2.1 Probability Concepts for Univariate Random Number Generation

The distribution of a continuous random variable X (the term "continuous" indicates that the random variable is defined over a continuum of values) is completely described by its probability density function f(x) (referred to as a PDF). The interpretation of the PDF is

that the area under f(x) over an interval a<x<b equals the probability that the random variable, X, will fall in the interval (a,b) and is denoted by P[a<X<b]. The integral of the f(x) over the entire support (the interval [L,U]) of X equals 1 (Strait 1989, p.24). The integral of the PDF from the lower bound L to some value x (that is less than the upper bound U) represents the probability that X will be observed in the interval (L,x). This integral operation defines the cumulative distribution function (CDF) for the random variable X. The CDF is denoted by F(x) and is represented mathematically by the equation

$$F(x) = \int_L^x f(s)\ ds \qquad\qquad (4.1)$$

The complementary cumulative distribution function (CCDF) is found from the simple relationship 1-F(X). It represents the probability that X will occur in the interval (x,U). The limits L and U do not necessarily have to be finite.

The inverse CDF, $F^{-1}(x)$, is single-valued if x is in the interval (L,U). Hence if p'= F(x') is known, in theory x'= $F^{-1}(p')$ exists. This inverse relation is important in the generation of random numbers on a computer. In practice there are situations for which no analytic expressions for F(x) or $F^{-1}(p)$ are available, so approximate numerical expressions are used instead.

4.2.1.1 Random Number Generation by the Probability Integral Transform Method

The probability integral transform (PIT) method for generating random variables is utilized. In the PIT method, the random variable of interest is expressed as a function of a U(0,1) random variable, where U(0,1) denotes the continuous random variable ranging uniformly over the interval (0,1). The PDF of the uniform random variable is g(u)=1 if u∈(0,1) and is zero elsewhere. The CDF for this random variable is G(u)=u. It can be shown that any CDF evaluated at a random value X (instead of being evaluated at a known value x) is distributed uniformly over the interval (0,1) (Mood et al. 1974, p. 202). Therefore, given a realization u of the U(0,1) random variable and a known statistical distribution, one can set u= F(x) and solve this equation to obtain x = $F^{-1}(u)$. The value x thus obtained is a realization from the desired statistical distribution.

In principle, one can obtain an exact solution for x given any statistical distribution and value u. In reality, there are some distributions, including the normal distribution and lognormal distributions, for which no closed-form analytical expression for F or F^{-1} exists. In these cases, approximations to the analytical expressions are applied.

The PIT method allows efficient sampling for the variable X from a subregion of the interval (L,U), such as (c,d) where L<c<d<U. The following steps are required:
- Find the corresponding interval in the uniform domain, say (c',d') from c'=F(c) and d'=F(d).
- Sample uniformly over the interval (0,1) to get a value u.

- Form the value u' corresponding to the subregion using the transformation u'=(d'-c')u+c'.
-

ranks of v_i. Although conceptually stratification divides the range of the variable X, say (L,U), the stratification can be accomplished using the uniform distribution over the interval [F(L),F(U)]. One value is randomly generated from each one of the n equi-probable subintervals of [F(L),F(U)]. The ith such sample can be obtained as:

$$w_i = \frac{(i-1) + u_i}{n} \qquad (4.3)$$

where u_i is a freshly generated (i.e., it is not the same as v_i), uniformly distributed number between 0 and 1. The w_i thus generated are ordered in increasing magnitude. In the final step, the w_i are reordered so that they have the same ranks r_i as the sequence v_i. The sample set thus obtained is random and stratified, lies between 0 and 1, and is uniformly distributed. Finally, the stratified values x_i from the distribution of X are obtained as $x_i = F^{-1}(w_i)$.

4.2.2.2 Imposing Rank Correlations

The LHS scheme described by Iman et al. (1982) can be further used to impose correlations between sampled variables. First, n samples of the p independent variables are generated using stratified sampling. Then, the sampled values for each of the variables are paired so as to impose a prespecified (rank) correlation between these variables. The process to choose the pairings is described here.

Assume that X_j, j=1,...,p are random variables that are correlated and their desired (p x p) rank correlation matrix is **C**. Assume that n samples are to be obtained. First, n stratified samples of each of the variables X_j are obtained as if they are independent. Let the sample matrix be **X** where

$$X = \begin{bmatrix} X_{11} & X_{21} & \cdots & X_{p1} \\ X_{12} & X_{22} & \cdots & X_{p2} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ X_{1n} & X_{2n} & \cdots & X_{pn} \end{bmatrix} \qquad (4.4)$$

Elements in the jth column of **X** are the samples of x_j, and each row of **X** is a sample vector containing one value of all p random variables. The objective is to rearrange the elements of columns of **X** so that the rank correlation will be as close to **C** as possible.

A rank matrix **R**=[r_{ij}] of the same size as **X** is constructed from the ranks of the samples x_{ij} in each column j, rather than the corresponding values X_{ij}. Because there are n samples of each random variable, r_{ij} will be one of the integers in the sequence {1,...,n}.

The next step is to obtain the Cholesky decomposition (Stewart, 1973, p. 142) of **C** as follows (because **C** is symmetric and nonnegative definite, such a decomposition always exists):

$$C = P P^T \tag{4.5}$$

where **P** is the lower triangular matrix and P^T is its transpose.

Next a score matrix **S** is generated by using van der Waarden scores. The functional form for the scores is

$$s_{ij} = f^{-1}(\frac{r_{ij}}{n+1}) \tag{4.6}$$

where ϕ^{-1} is the inverse of the standard normal CDF. By construction, **S** has the same rank correlation matrix as **X**.

Let **U** be the correlation matrix of **S**, whose Choleski decomposition can be written as

$$U = Q Q^T. \tag{4.7}$$

We want to determine a matrix **T** such that

$$C = TU T^T. \tag{4.8}$$

Substituting for **C** and for **U** this expression leads to the expression

$$P P^T = TQ Q^T T^T \tag{4.9}$$

which yields

$$T = PQ^{-1} \tag{4.10}$$

Although the rows of **X** were generated independently the sample rank correlation matrix, **U**, will not equal the identity matrix. The above algorithm calculates Q^{-1} that can be used to effectively remove the unwanted correlations.

A new score matrix, **S*** is now determined from

$$S^* = S T^T \tag{4.11}$$

which has correlation matrix **C** by construction.

A new rank matrix $\mathbf{R}^*$ is now obtained by replacing elements of $\mathbf{S}^*$ by their column ranks. Finally, the columns of the sample matrix $\mathbf{X}$ are rearranged so that it has rank matrix $\mathbf{R}^*$.

4.2.2.3 Insuring a Positive-Definite of Correlation Matrix

A properly specified correlation matrix $\mathbf{C}$ is real-valued, symmetric and positive-definite. If $\mathbf{C}$ is not positive-definite, it will not have full rank, and consequently one or more of the columns of $\mathbf{X}^*$ will be (approximately) linearly related. If $\mathbf{X}^*$ does not have full column rank, it cannot be used as for regressor variables in a sensitivity analysis.

Because $\mathbf{C}$ is real-valued and symmetric by construction, an equivalent condition for positive-definiteness is that the each of the eigenvalues, $\{\lambda_i\}$, be positive (Stewart, 1973, p. 309). A test can be designed to check whether $\mathbf{C}$ is positive-definite. If $\mathbf{C}$ is not positive-definite, it can be modified to be positive-definite. The algorithms for determining the condition of $\mathbf{C}$ and modifying $\mathbf{C}$ are discussed below.

4.2.2.3.1 Obtaining Eigenvalues and Eigenvectors

To obtain the eigenvalues of $\mathbf{C}$, $\mathbf{C}$ is first transformed into a tridiagonal matrix $\mathbf{A}$,

$$A = PCP \tag{4.12}$$

where $\mathbf{P}=\mathbf{P}_1\mathbf{P}_2...\mathbf{P}_{p-2}$, $\mathbf{P}$ is the accumulated Householder reduction matrix and $\mathbf{P}_i$ is the reduction matrix at the ith stage of the transformation (Householder 1964; Press et al., 1988). The eigenvalues $\mathbf{l}_i$ and eigenvector matrix $\mathbf{E}'$ of $\mathbf{A}$ are computed, and the eigenvector matrix $\mathbf{E}$ of $\mathbf{C}$ is then obtained as $\mathbf{E}=\mathbf{PE}'$. The eigenvalues of $\mathbf{C}$ are the same as those of $\mathbf{A}$.

The eigenvalues and eigenvectors of $\mathbf{A}$ are obtained via the implicit shift QL algorithm (Press et al., 1988). The matrix $\mathbf{A}$ can be decomposed into

$$A = QL \tag{4.13}$$

where $\mathbf{Q}$ is an orthogonal matrix and matrix $\mathbf{L}$ is lower triangular. The distinct eigenvalues of $\mathbf{A}$ are obtained as the diagonal elements of the $\mathbf{L}$ matrix (having only zero elements on their immediate right off-diagonal) and the remaining diagonal elements are part of diagonal block(s) of the same order(s) as the multiplicity(s) of the remaining eigenvalues. The multiplicant eigenvalues of $\mathbf{A}$ are the eigenvalues of these diagonal block submatrices. The implicit shift QL algorithm continues the diagonalization until all eigenvalues are taken from the diagonal, even in cases of multiplicity of eigenvalues. In cases of zero eigenvalues, correct eigenvectors are still computed correctly.

4.2.2.3.2 Adjusting the Correlation Matrix

If the eigenvalues of **C** are not all positive, it can be modified to obtain another correlation matrix **C'** that is positive-definite. The new matrix **C'** is close to **C** in the sense that it has the same eigenvectors and many of the same eigenvalues.

Because **C** is symmetric, it can be decomposed as

$$C = E \Lambda E^T \tag{4.14}$$

where **E** is the matrix of column eigenvectors and **L** is the diagonal vector of corresponding eigenvalues. Let **L'** be the diagonal matrix of elements modified from **L** in that any diagonal entry smaller than ε is replaced by ε. A recommended value for ε is 10^{-5}. The matrix **G** is then formed from **E** and **L**

$$G = E \Lambda' E^T. \tag{4.15}$$

The matrix **G** is not a correlation matrix (some of its elements may exceed 1 in magnitude) but it is positive-definite. The modified correlation matrix **C'** can be formed element-wise from **G** using the relationship

$$c_{ij} = \frac{g_{ij}}{\sqrt{g_{ii} \, g_{jj}}}. \tag{4.16}$$

4.2.3 Statistical Distributions

The statistical distributions available for use in GENII-V2 are summarized in Table 4.1.

Truncation of the range of a statistical distribution is sometimes warranted because of physical limitations. The ability to truncate the range of random variables is implemented in GENII. Truncation information is given in Table 4.2 for each statistical distribution. The implementation shall allow truncation of one or both tails of a distribution. If two truncation limits are entered the second limit must be greater than the first.

4.2.3.1 Algorithms for the Uniform Distribution

Algorithms that generate truly random uniform numbers do not exist, although many algorithms generate pseudo-random deviates (hereafter loosely referred to as random numbers). The selection of a random-number generator is based on four considerations:
- computer implementability
- degree of independence within a sequence of deviates
- periodicity or cyclic length of a sequence
- uniform coverage of sequences (occurrence) over the interval (0,1), the square (0,1) X (0,1), and so on, up to the hypercube on (0,1) in k dimensions.

Table 4.1 Statistical Distributions Implemented in GENII-V2

Index	Distribution	Parameters
0	Constant	Single value
1	Uniform	Lower limit and upper limit
2	Loguniform (base e)	Lower limit and upper limit are in data (not log) units.
3	Normal	Mean and standard deviation.
4	Lognormal (base e)	Mean and standard deviation of the underlying normal distribution.
5	Triangular	Lower limit, mode, and upper limit.
6	User Supplied	Table of n pairs of values (x_i, p_i). The x_i must be unique and ordered in increasing value. The p_i must be unique and ordered in increasing value with $p_1=0.0$ and $p_n=1.0$.

Table 4.2 Truncation of Statistical Distributions

Index	Distribution	Truncation Information
0	Constant	Not applicable
1	Uniform	The lower and upper truncation limits need to be in the range (a,b) of the defined uniform distribution.
2	Loguniform (base e)	The lower and upper truncation limits need to be defined in data (not log) units.
3	Normal	Any lower and upper truncation limits are available. Truncation limits further than 6 standard deviations from the mean are essentially ignored.
4	Lognormal (base e)	Any lower and upper truncation limits greater than zero are allowable. The truncation limits are entered in the data (not log) units.
5	Triangular	The lower and upper truncation limits need to be in the range (a,b) of the defined uniform distribution.
6	User Supplied	The lower and upper truncation limits need to be in the range (a,b) of the user supplied distribution.

Linear congruential methods (Kennedy and Gentle 1980, pp. 136, 150) are commonly used on digital computers. The SUM[3] processor called by GENII-V2 uses a linear congruential random-number generator.

4.2.3.1.1 Generation Algorithm

The uniform distribution algorithm consists of a uniform (0,1) generator and a uniform (a,b) generator.

4.2.3.1.1.1 Uniform (0,1) Generator

A linear congruential generator generates random integers using an algorithm of the form

$$R_i = (A \bullet R_{i-1} + C) \bmod M \qquad (4.17)$$

where R_i is the ith random integer to be generated between 1 and M-1, A and C are constants, M is the modules of the generated integers, and mod denotes the remainder function. These integers are converted to approximate U(0,1) numbers by the division

$$U_i = R_i / M . \qquad (4.18)$$

The period of a sequence $\{U_i\}$ of generated deviates is the minimal value k such that $U_i = U_{i+k}$ (this occurs independent of i for linear congruential generators). It can be shown that the period of any congruential generator does not exceed M. Therefore, if one is generating many uniform deviates, it is desirable that M be large. The performance of each congruential generator (each choice of A, C, and M) can thus be examined with respect to criteria proceeding from the four considerations given above. The SUM[3]/GENII-V2 implementation uses A=16807 and M=2147483647. These choices of A and M yield a sequence $\{U_i\}$ that:
- is implementable on a 32-bit computer without machine language coding
- is sufficiently independent on an element-by-element basis
- possesses a long cycle (period)
- has a reasonable degree of coverage over all hypercubes of dimension less than k.

These attributes proceed from results from tests described by Fishman and Moore (1986).

4.2.3.1.1.2 Uniform (a,b) Generator

The uniform distribution on the interval (a,b) will be denoted by U(a,b). Any value x generated from the uniform (a,b) distribution in the GENII system makes use of a value y from the U(0,1) distribution. The value y is generated first, then x is evaluated as x = a+(b-a)y.

4.2.3.2 Algorithm for the Loguniform Distribution

Loguniform distributions have a uniform distribution of the exponent.

4.2.3.2.1 Definition of the PDF

The PDF for a loguniform random variable of base b is

for -∞<c<d<∞, where I is an indicator function (0 if false, 1 if true), b is the logarithm base, and ln(b) denotes the natural logarithm of b.

4.2.3.2.2 CDF and Inverse CDF Algorithms

The CDF algorithm for the loguniform distribution is

The logarithm base b is chosen to be the natural constant e. The i 0 rg he logarithm base b is cho1 Tc 0 Tw T

4.2.3.3.2 CDF Algorithm

A $N(\mu,\sigma^2)$ random deviate, y, is obtained by generating a $N(0,1)$ deviate, x, then transforming as $y = \mu+\sigma x$. This description of the generation of normal random variables will therefore focus on the $N(0,1)$ parameterization.

The first step in the algorithm for the CDF of the standard normal distribution is to compute the area in the smallest "tail," evaluated from x to the lower or upper limit of the range of x, depending on the sign of x. Let T(x) be that area defined as T(x)=Prob[X<s] for s<0, or Prob[X>s] for s$\geq$0. Thus F(x)=T(x) for x<0 and F(x)=1-T(x) for x$\geq$0. The approximation used for T(x) is that of Adams (1969) and is given by

$$T(x) = 0.5 - z\left((a_1 + a_2\, y) / (y + a_3 + a_4) / [y + a_5 + a_6) / (y + a_7)]\right) \qquad (4.22)$$

for $|x| \leq 1.28$,

$$T(x) = b_1 \exp(-y) / ((z + b_2 + b_3) / [(z + b_4 + b_5) /$$
$$((z + b_6 + b_7) / (z + b_8 + b_9) / [(z + b_{10} + b_{11}) / (z + b_{12})])])\qquad (4.23)$$

for $1.28 < x \leq$ UTZERO or $1.28 < -x \leq$ LTONE, and T(x)=0 for x>UTZERO or x<-LTONE. The algorithm uses z=|x| and $y = z^2/2$. Values for the coefficients a_i and b_i are given in Table 4.3.

A FORTRAN implementation of this algorithm is available in Hill (1985). The values UTZERO and LTONE are machine-dependent. The variable UTZERO represents the upper tail limit of the statistical density such that P[X>UTZERO] = 0 at machine accuracy, and LTONE represents the lower tail limit such that P[X>LTONE] = 1 at machine accuracy. If n denotes the decimal length of real numbers for the machine being used, and w denotes the smallest allowable positive real number, LTONE = (n+9)/3 and UTZERO = -0.3+[-2ln(w)-2]$^{0.5}$.

4.2.3.3.3 Inverse CDF Algorithm

The inverse CDF for the $N(0,1)$ random variable is approximated by

$$F^{-1}(p) = \begin{array}{l} q\, A(q^2)/B(q^2) \quad \text{if } |q| < 0.42 \\ \text{sgn}(q)\, C(r)/D(r) \quad \text{if } |q| \geq 0.42 \end{array} \qquad (4.24)$$

where q = p-0.5, and r = (ln(0.5-|q|))$^{0.5}$. The quantity (0.5-|q|) is formed as p or, to avoid cancellation if p is small, as (1-p). The letters A, B, C, and D represent polynomials of order 3, 4, 3, and 2, respectively, whose coefficients are given by Beasley and Springer (1985), and sgn(q) = 1 if q > 0 and -1 if q < 0.

Table 4.3 Coefficients in the Normal CDF Algorithm

i	a_i	b_i
1	0.398942280444	0.398942280385
2	-0.399903438504	-3.8052E-8

12	NA	3.99019417011

4.2.3.3.4 Precision

The approximation for the normal CDF is accurate to 9 decimal digits on a machine with that accuracy (Hill 1985). The algorithm is implemented in double precision, so it achieves the desired accuracy on a machine with a 32-bit word length.

The polynomial approximation for the inverse normal CDF is accurate up to 2^{-31} in the domain of p [e.g., $|p'-p| < 2^{-31}$, where p' is the actual value of $F(x_{p'})$]. Consideration of roundoff error brings the accuracy to the order of 20 times the least significant bit in the machine's mantissa (in the domain of p). The actual accuracy of x_p is of concern, however, and is linearly approximated by

$$x_{p'} - x_p = \sqrt{(2p)}\ (p' - p)\ e^{(0.5\, x_{p'}^2)} \tag{4.25}$$

This error approximation is identical (up to a constant) for the truncated distribution.

4.2.3.4 Algorithm for the Lognormal Distribution

The right-skewed lognormal distribution is frequently used to approximate distributions of variables found in nature.

4.2.3.4.1 Definition of the PDF

A random variable is said to be lognormally distributed when its logarithm is distributed as a normal $N(\mu,\sigma^2)$ random variable. The PDF of the lognormal distribution is

$$f(x) = \frac{e^{\frac{[\log(x)-m]^2}{2s^2}}}{x\,s\,\sqrt{(2p)}} \; I(0 < x < \infty). \qquad (4.26)$$

4.2.3.4.2 Generation Algorithms

In the SUM[3]/GENII-V2 system, a lognormal random variable x is obtained by transforming a $N(\mu,\sigma^2)$, y, using the expression $x=e^y$. The loguniform CDF is evaluated for a value x by computing $y=\ln(x)$ and using y in the algorithm for the $N(\mu,\sigma^2)$ algorithm.

Truncation limits specified for the lognormal distribution are converted to limits in the normal domain, then further converted to appropriate limits in the U(0,1) domain as described in the section on the normal distribution. Thus, the generation algorithm for the truncated distribution uses a subset of the U(0,1) distribution in the algorithm for the untruncated distribution.

4.2.3.4.3 Precision

The precision of the lognormal generation algorithm can be obtained approximately using the first two terms of the equation

$$b^{y_{p'}} = \big((p'-p)\,s\,\exp\,(y_{p'}^2/2)\,\ln(b)\,\_\,(2p)\big) +$$
$$\big(0.5(p'-p)^2\,p\,s\,\ln(b)\,\_\,\exp\,(y_{p'}^2)\,[y_{p'}+2s\,\ln(b)\big) + o\big[(p'-p)^2\big] \qquad (4.27)$$

where o(s) is a collection of terms in s such that $\lim_{s\to 0} o(s)/s = 0$, y_p is the theoretical realization from the normal $N(\mu,\sigma^2)$ distribution associated with uniform realization p, and $y_{p'}$ is the value actually obtained ($y_{p'}$ is exact for the value p', which did not occur). Thus $y_{p'}$-y_p is the error (in the normal domain) caused by the algorithm approximation and computer implementation of the algorithm, and err_e, the error of the lognormal deviate, is found from

$$err_e = b^{y_{p'}} - b^{y_p p}. \qquad (4.28)$$

The bound on |p'-p| is given in the description of the normal deviate generation.

$$\sum_{i=k_1}^{k_2-1} \text{bin}_i^{n,p} = \sum_{i=k_1}^{n} \text{bin}_i^{n,p} - \sum_{i=k_2}^{n} \text{bin}_i^{n,p} \tag{4.29}$$

4.2.3.5 User-Specified Distribution

In addition to selecting from the foregoing families of distributions, the user may implement any other distribution by supplying a table of data pairs corresponding to [x,F(x)]. Thus, the user can provide SUM^3/GENII-V2 with discrete evaluations of the CDF. The algorithm linearly interpolates between these points to solve for $F^{-1}(u)$ when generating a deviate or determining truncation limits in the domain of the uniform U(0,1) distribution.

4.3 <u>UNCERTAINTY ANALYSIS METHODS</u>

The analysis of uncertainty entails using one or more tools to present the uncertainties in output results and their statistics. This section describes the tools for uncertainty analysis that are available in the SUM^3/GENII-V2 system.

4.3.1 <u>CDF's and CCDF's</u>

The cumulative distribution function, F(x), for a random variable (Mood et al., 1974), X, is cumulative probability or probability that a realization of X will not exceed a given value, $F(x) = \text{Prob}[X \leq x]$. This function is nondecreasing and takes on values from 0 to 1.

A slowly increasing CDF indicates a large variability of X, while a rapid increase in the CDF reflects a smaller degree of variability of X. If X is continuously distributed, the inflection point of the CDF occurs at the mode of the distribution.

The 100pth percentile of the distribution is obtained as

$$\boldsymbol{x}_p = \text{minimum} \quad \{\, x : F(x) \geq p \,\} \tag{4.30}$$

If X is from a continuous distribution and 0<p<1, then

$$\boldsymbol{x}_p = F^{-1}(p). \tag{4.31}$$

For example, the median (50th percentile) and the 90th percentile are obtained as above using p=.5 and p=.9, respectively.

Because the true cumulative distribution function is generally not known, the empirical cumulative distribution function is used as an estimate of the CDF. Given the observed data $x_1,...,x_n$, the empirical distribution function is computed as:

$$F_n(x) = \frac{1}{n} \sum_{i=1}^{n} \boldsymbol{d}(x_i \leq x). \tag{4.32}$$

where $\delta(A)$ is 1 or 0 according as A is true or false. Although the empirical CDF, being a sum of step functions, is discontinuous for small sample sizes, as n gets large, this function becomes increasingly continuous and smooth if X is from a continuous probability distribution. If one is interested in exceedence probabilities rather than cumulative probabilities, the CCDF, $\mathbf{G}_n$, can be more useful than the CDF. $G_n(x)$ is obtained as $G_n(x) = 1-F_n(x)$.

4.3.2 Sample Mean, Quantiles and their Corresponding Confidence Limits

4.3.2.1 Sample Mean and Confidence Limits

The sample mean, defined as

$$\overline{x}_n = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{4.33}$$

is commonly used as an estimate for the population mean, μ (=E[X]). Because the sample mean is also random, the degree of its uncertainty is frequently expressed as a $100(1-2\alpha)$ percent (random) confidence interval $[l_\alpha, u_\alpha]$ such that the statement $\text{Prob}[l_\alpha \leq \mu \leq u_\alpha] = 1-2\alpha$. The confidence interval computed in the GENII system is the interval is based upon the normal-theory approximation,

$$\overline{x}_n + \frac{1}{\sqrt{n}} t_{n-1}^a s_n \tag{4.34}$$

where

$$s_n = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \overline{x}_n)^2} \tag{4.35}$$

and t_{n-1}^a 34is the upper $100(1-\alpha)$th quantile of the Student t distribution having n-1 degrees of freedom.

Letting m=n-1, if n-1$\geq$100 the upper $100(1-\alpha)$th quantile of the normal distribution, z^α, is used in lieu of the t distribution. This normal quantile is computed as in Section 2.3.3.2. If n-1<100 the quantile from the t distribution is used, being obtained as (Kennedy et al., 1980)

$$t_m^a = z^a + \frac{z^{a3}+z^a}{4m} + \frac{5z^{a5}+16z^{a3}+3z^a}{96m^2} + \frac{3z^{a7}+19z^{a5}+17z^{a3}-15z^a}{384m^3} \tag{4.36}$$

where z^α is the value from the normal (0,1) distribution satisfying $F(z)=1-\alpha$.

4.3.2.2 Sample Quantile and Confidence Limits

The sample quantile is obtained as follows:

$$\hat{x}_p = \text{minimum} \quad \{\, x_i : F_n(x_i) \geq p \,\}. \tag{4.37}$$

For moderately large n, it is acceptable to obtain the lower and upper confidence limits from the ordered data $x_{(1)},...,x_{(n)}$ using the binomial approach. It follows from the definition of ξ_p that

$$\text{Prob}[k_1 < n\, F_n(\boldsymbol{x}_p) \leq k_2] = \text{Prob}[X_{(k_1)} < \boldsymbol{x}_p \leq X_{(k_2)}] \tag{4.38}$$

Consequently the k_1st and k_2nd smallest values can respectively be used as the lower and upper confidence limits for ξ_p. Because $nF_n(\xi_p)$ is distributed as binomial distribution, a $100(1-2\alpha)$ percent confidence interval for ξ_p can be computed by determining those values of k_1 and k_2 which minimize $k_2 - k_1$ subject to

$$\sum_{i=k_1}^{k_2-1} \binom{n}{i} p^i (1-p)^{n-i} \geq 1 - 2a \tag{4.39}$$

As n is reduced the result could occur that one or both of the lower and upper confidence limits may respectively be $x_{(1)}$ and $x_{(n)}$. This possibility increases for even moderate sample sizes as p becomes significantly larger or smaller than .5.

The previous equation can be evaluated (exactly) from

$$\sum_{i=k_1}^{k_2-1} \binom{n}{i} p^i (1-p)^{n-i} = I_p(k_1, n-k_1+1) - I_p(k_2, n-k_2+1) \tag{4.40}$$

where $I_p(a,b)$ is the incomplete beta function (Majumder and Bhattacharjee 1985)

$$I_p(a,b) = \frac{1}{B(a,b)} \int_0^p p\, t^{a-1}(1-t)^{b-1}\, dt \tag{4.41}$$

and

$$B(a,b) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} \tag{4.42}$$

For integer a (which applies here), $\mathbf{G}(a)=(a-1)!$. An approximation for $I_p(a,b)$ is available (Press et al., 1988).

Let $w = (np(1-p))^{0.5}$ and let $z_{\alpha/2}$ be the $100(1-\alpha/2)$ upper percentile of the Normal(0,1) distribution. Initial values for K1 and k2 are found from:

$$k_1 = np - w\,z_{a/2} + 0.5$$
$$k_2 = np + w\,z_{a/2} + 0.5$$

(4.43)

These initial values of k_1 and k_2 are accurate to within 1 or 2 for all n greater than 20.

5.0 ATMOSPHERIC TRANSPORT AND DEPOSITION MODULES

The atmospheric models, ACUTESRC, CHRONSRC, PUFCHRON, and PUFACUTE, for the GENII-V2 system, are a suite of codes to account for the transport, diffusion, deposition, depletion, and decay of radionuclides while in the atmosphere. The basic diffusion model used in this suite of codes is the Gaussian solution to the diffusion equation. Both straight-line Gaussian-plume (ACUTESRC and CHRONSRC) and Lagrangian-puff (PUFCHRON and PUFACUTE) models are incorporated in the suite of codes. The models include estimations for both chronic (CHRONSRC and PUFCHRON) and accidental or acute (ACUTESRC and PUFACUTE) releases. Elements of the models representing the physical processes of diffusion, deposition, depletion, cloud shine, and decay of radionuclides have been selected to be as realistic as possible yet be consistent with readily available meteorological and climatological data. In the case of diffusion coefficients and the effects of building wakes, alternative models for these physical processes have been included in the suite to provide users with flexibility.

In the rest of this section includes the descriptions of both the straight-line plume and puff models and its components. Section 5.1 describes the straight-line plume, while Section 5.2 describes the puff models. The components of the models are described in Section 5.3. The optional air submersion dose calculations performed by these models are described in Section 5.4.

5.1 STRAIGHT-LINE GAUSSIAN PLUME MODEL

This section describes the straight-line Gaussian model. It covers the basic plume and its variations. It also describes modification of the model to account for area sources, multiple sources, and the finite flow from short stacks and vents.

5.1.1 Basic Model

The complete straight-line Gaussian plume model is

$$\frac{c(x, y, z, H, h_{eff})}{Q'(x)} = \frac{1}{2\pi\, U(h_s)\, \boldsymbol{s}_y \boldsymbol{s}_z} \exp(-\frac{y^2}{2\boldsymbol{s}_y^2}) G(z) \tag{5.1}$$

where c = the concentration at distance x, crosswind position y, and height z, in a
plume with axis at height h_{eff} (Ci/m^3)
$Q'(x)$ = the release rate, corrected for deposition and decay as appropriate (Ci/s)
$U(h_s)$ = the wind speed at release height, h_s (m/s)
s_y = the horizontal diffusion coefficient (m)
s_z = the vertical diffusion coefficient (m)
$G(z)$ = the vertical dispersion factor.

The vertical factor includes plume reflection off the ground and the mixing layer and is given by

$$G(z) = \sum_{n=-\infty}^{\infty} \exp\left[-\frac{(2nH + (h_{eff} - z))^2}{2s_z^2}\right] + \exp\left[-\frac{(2nH - (h_{eff} + z))^2}{2s_z^2}\right]$$ (5.2)

where h_{eff} = the effective release height (h_s + plume rise) (m)
H = the mixing layer thickness (m).

The limits of the summations in Equation 5.2 can be truncated to n from -2 to +2 without significantly reducing the accuracy of the equations. In the plume models, the receptor height (z) is assumed to be 1 meter.

For the case of release height above the atmospheric mixing layer, the top of the mixing layer serves as a permeable surface for material approaching the surface from above, and a reflecting surface for material reflected from the ground. G(z) for this case is still given by (2) with the following modifications: if $n < 0$, then only the exponential with 2nH - (h + z) is summed; if $n > 0$, then only the exponential with 2nH + (h_e - z) is summed; and if $n = 0$, both exponentials are summed.

This model is appropriate for short duration releases. Typically, it is used to estimate hourly-average concentrations. Release rates for depositing or decaying effluents must be adjusted to account for deposition and decay to maintain mass continuity for the effluent. If the release rate is not adjusted, the equation will systematically overestimate the concentration, and the magnitude of the overestimate will increase with increasing distance from the source. The wind speed at release height is used for elevated releases. If the release is at or near ground level, the 10-meter wind speed generally replaces the release-height wind speed. For these codes, releases below 12 meters use the 10-meter wind speed. Empirical parameterizations, based on experimental data, are commonly used to estimate the effective release height and the diffusion coefficients, which are discussed later in Section 5.3.3.

If the distance from the source is sufficiently large, the vertical diffusion coefficient approaches the mixing thickness in magnitude signifying that the effluent is uniformly mixed in the vertical. Under this condition, the straight-line Gaussian model can be simplified to

$$\frac{c(x, y, z)}{Q'(x)} = \frac{1}{\sqrt{2p}\ U(h_s)\ H_u\ s_y} \exp\left[-\frac{1}{2}\left(\frac{y}{s_y}\right)^2\right]$$ (5.3)

where H_u = The height of uniform depth which is the mixing layer or the effective release height, whichever is higher.

In the codes, the effluent is considered to be uniformly mixed in the vertical when the vertical diffusion coefficient is 1.2 times the uniform depth.

5.1.2 Sector-Average Model

It is unlikely that a plume will remain in the same location for prolonged periods. Therefore, a sector-average plume model is used for chronic or long duration releases. The sector-average model is derived by integrating the straight-line plume model crosswind and dividing the result by the sector width. Historically, a 22.5? (2? radians/16 sectors) sector width has been used because wind directions were recorded by sector (N, NNE,...S,...NNW).   However, since 1965 directions have been recorded in tens of degrees.

The sector average model is

$$\frac{c(q, r, z)}{Q'(r)} = \frac{1}{\sqrt{2p}\ U\ s_z\ q_w} G(z)$$ (5.4)

where $?(?_i, r, z)$ = the concentration at distance r, in sector $?_i$, at height z (Ci/m^3)
 $Q'(r)$ = the total mass of material released corrected for deposition and decay
 $?_w$ = the sector width, which is the larger of the arc length in a 22.5° wide sector or 4 times s_y
 U = wind speed, m/s
 s_z = vertical diffusion coefficient for distance r (or time t = x/U)
 $G(z)$ = vertical factor given by Equation (5.2)

Note that the sector-average model is given in cylindrical coordinates and the straight-line plume model is given in Cartesian coordinates. This follows the normal convention in the literature.

At long distances, the model further simplifies, due to uniform mixing in the vertical, to

$$\frac{c(q, r, z)}{Q'(r)} = \frac{1}{U\ H_u\ q_w}$$ (5.5)

As in the basic model, the code assumes that the plume is uniformly mixed in the vertical when s_z is 1.2 times the uniform depth.

5.1.3   Area Source Model

The area source model starts with the following assumptions:

1)   The area is a square with dimension 2a.

2)   The square is centered on the origin and oriented with sides parallel and perpendicular to the wind direction. (The orientation of the square rotates with the wind.)   If the x-axis is aligned with the transport direction, the square covers the area defined by $-a < x < a$, $-a < y < a$.

3)   Material is released at a uniform rate, Q_A, which has units of mass/ (area x time). The equivalent point source release rate is $4a^2 Q_A$.

Two area source models are provided: a centerline model and a sector-averaged model.

5.1.3.1 Centerline Area Model

The concentration in the plume from an area source is determined as a function of the distance from the upwind edge of the area and the crosswind position. For receptors with x-coordinates $> -a$ and ? a, the concentration is given by

$$c(x, y, z) = \int_{-a}^{x} \frac{Q_A}{\sqrt{2p}\ s_z(x-z)\ U} G(z,z)\{\frac{1}{2}(erf[\frac{a+y}{\sqrt{2}\ s_y(x-z)}] + erf[\frac{a-y}{\sqrt{2}\ s_y(x-z)}])\}dz \quad (5.6)$$

where ? is the variable of integration, erf is the error function, and G(z,?) is Equation (5.2) except s_z is $s_z(x-?)$.

For receptors with x-coordinates $> a$, the concentration is given by

$$c(x, y, z) = \int_{-a}^{a} \frac{Q_A}{\sqrt{2p}\ s_z(x-z)\ U} G(z,z)\{\frac{1}{2}(erf[\frac{a+y}{\sqrt{2}\ s_y(x-z)}] + erf[\frac{a-y}{\sqrt{2}\ s_y(x-z)}])\}dz \quad (5.7)$$

Analytical solutions of the integrals in Equations (5.6) and (5.7) do not exist. The integrals are solved numerically. The codes use a Simpson's Integration scheme to estimate the integrals.

At large downwind distances the concentrations can be estimated by assuming that the dispersion coefficients are independent of ?. That is, the concentration can be estimated by

$$c(x, y, x) = \frac{2a\ Q_a}{\sqrt{2p}\ s_z\ U} G(z)\{\frac{1}{2}(erf[\frac{a+y}{\sqrt{2}\ s_y(x)}] + erf[\frac{a-y}{\sqrt{2}\ s_y(x)}])\} \quad (5.8)$$

where the 2a comes from the integration. The distance at which the concentrations predicted by Equation (5.7) approaches the concentration predicted by Equation (5.8) is a function of the atmospheric stability and a function of the way in which s_y and s_z are parameterized. For all

stability classes and diffusion parameterization schemes, concentrations using Equation (5.7) and Equations (5.8) are within about 1% when the distance is 10 times a.

When s_z becomes 1.2 time the mixing height, Equation (5.8) can be simplified to

$$c(x, y, z) = \frac{2\,a\,Q_a}{U\,H}\{\frac{1}{2}\,(erf\,[\frac{a+y}{\sqrt{2}\,\boldsymbol{s}_y(x)}]+erf\,[\frac{a-y}{\sqrt{2}\,\boldsymbol{s}_y}])\} \qquad (5.9)$$

5.1.3.2 Sector-Averaged Area Model

In sector-average models, dispersion of material released from area sources are treated by considering three regions: The source region, an intermediate region, and a sector-average region. Concentrations in the source region are calculated using following equation:

$$c(\boldsymbol{q},r,z) = \int_{-a}^{r}\frac{Q_A}{\sqrt{2\boldsymbol{p}}\,\boldsymbol{s}_z(r-\boldsymbol{z})\,U}G(z,\boldsymbol{z})\,d\boldsymbol{z} \qquad (5.10)$$

Equation (5.10) is the same as Equation (5.6) except that the term involving the error function has been deleted. In effect, deleting the error function term neglects lateral diffusion.

The intermediate region extends from the downwind edge of the source to the distance at which the arclength of the sector equals the width of the source. When there are 16 sectors this distance, r_{16}, is

$$r_{16} = \frac{a}{(\boldsymbol{p}/16)} = 5.093\,a \qquad (5.11)$$

In the intermediate region the concentration is given by

$$c(\boldsymbol{q},r,z) = \int_{-a}^{a}\frac{Q_A}{\sqrt{2\boldsymbol{p}}\,\boldsymbol{s}_z(r-\boldsymbol{z})\,U}G(z,\boldsymbol{z})\,d\boldsymbol{z} \qquad (5.12)$$

Equation (5.12) is Equation (5.7) without lateral diffusion.

Farther downwind, the lateral diffusion is proportional to 1/r, as it is in the point-source, sector-average model. In this region the concentration is calculated from

$$c(r,0) = \frac{r_{16}}{r} \int_{-a}^{a} \frac{2Q_A}{\sqrt{2p} \; s_z(r-z) \; U} \exp[-\frac{1}{2}(\frac{h_e}{s_z(r-z)})^2] dz \tag{5.13}$$

Eventually, as the distance from the origin increases, the sector-average concentration from an area source converges to the sector-average concentration for a point source. The sector-average model for a point-source is

$$c(q,r,z) = \frac{Q_p \, G(z)}{\sqrt{2p} \; s_z(r) \; U \frac{2p\,r}{16}} \tag{5.14}$$

where Q_p ($= 4aQ_a$) is the point equivalent to the area source.

For the diffusion parameterizations in the code, the area sector-averaged model is within 1% of the point sector-averaged model for distance of 5a. Because the intermediate region occurs at a distance greater than 5a, in the codes there are only two regions: the source region (Equation (5.10)) and the sector-average point-source (Equation 5.14).

5.1.4 Finite Source Correction

The equations presented to this point all assume that the release flow is negligible. This assumption is not valid for releases from short stacks and vents if the receptor is near the release point. If the flow from the stack is neglected the result may be concentration estimate in atmosphere that exceed the concentration in the stack. In simple cases, this unwanted result can be avoided by modification of the equations to include the stack flow in the denominator of the leading term on right hand side of the equations. For example, Equation (5.1) becomes

$$\frac{c(x,\,y,\,z,\,H,\,h_{\text{eff}})}{Q'(x)} = \frac{1}{2p\,U(h_s)\,s_y\,s_z + f\,0} \exp(-\frac{y^2}{2s_y^2}) \, G(z) \tag{5.15}$$

where f0 is the stack flow in cubic meters per second.

Unfortunately, this simple modification does not work in all instances. A more general correction can be made by assuming the dilution in the stack and atmosphere are additive in manner of resistances in a parallel electrical circuit. If the concentration calculated assuming a point source is denoted by $(X/Q)^*$, and f0 is the flow, then the correct concentration in the atmosphere near the source would be

$$\frac{c}{Q} = \frac{1}{[\,(\frac{c}{Q})^*\,]^1 + f\,0} \tag{5.16}$$

5.1.5 Multiple Sources

On occasion it may be necessary to consider the combined effects of releases from more than one source within the context of a straight line plume model. This is accomplished by establishing a polar grid, determining the position of each source within the grid, and calculating the position of the receptors relative to the source. For the acute model, all the sources are assumed to be co-located at the center of the grid. For the chronic models, sources are allowed to be located anywhere on the grid. The positions of the sources are specified by distance and direction from the origin of this grid.

The following convention is used for treatment of multiple sources with the straight-line plume models. A polar grid is defined, and the sources are specified by the distance and direction from the origin of this grid. Source definition is completed when the number of sources, m, is defined and a position is specified for each source. Table 5.1 shows a symbolic representation of a complete definition of source positions (assuming the first source is located at the center of the grid). In general, the position of source m is given by coordinates $(r_{sm}, ?_{sm})$, where the subscript s indicates source and the subscript m identifies the specific source.

The position of each receptor must be specified in polar grid coordinates. Specification of the position of receptors by polar grid coordinates is sufficient if there is only one source or the if sources are collocated. In the general case, however, the position of each receptor must be determined with respect to each source. Given source and receptor locations in polar grid coordinates, the distance from a source m to a receptor n can be calculated by:

$$r_{mn} = [\, r_{sm}^{\,2} + r_{rn}^{\,2} - 2\, r_{sm}\, r_{rn}\, \cos(\boldsymbol{q}_{sm} - \boldsymbol{q}_{rn})\,]^{1/2} \qquad (5.17)$$

The bearing from source m to receptor n can be calculated by

$$\boldsymbol{q}_{mn} = \tan^{-1}\!\Big[\ \frac{r_{sm}\sin(\boldsymbol{q}_{sm}) - r_{rn}\sin(\boldsymbol{q}_{rn})}{r_{sm}\cos(\boldsymbol{q}_{sm}) - r_{rn}\cos(\boldsymbol{q}_{rn})}\ \Big] \qquad (5.18)$$

Table 5.1. Source position definition

Source	Distance	Direction
1	0	0
2	r_{s2}	$?_{s2}$
...	...	...
m	r_{sm}	$?_{sm}$

Upon completion of calculation of the positions of all receptors with respect to all sources, a matrix similar to that shown in Table 5.2 will have been filled. This matrix provides the information necessary to compute the total concentrations at each receptor. However, the information is not organized in a manner that promotes computational efficiency. To promote computational efficiency, the information in Table 2 will be sorted and reorganized. When the reorganization is complete the revised source/receptor position matrix will have the appearance of Table 5.3.

Given the wind direction, the relationships shown in Table 5.3 can be used to quickly identify all receptors downwind of each source. Each receptor will appear just once for each source. However, the revised source/receptor matrix may be larger than the initial matrix because for a given wind direction there may not be an equal number of receptors downwind of all sources. For example, for the first downwind direction Table 5.3 shows two receptors downwind of source 1 and three receptors downwind of source m.

Table 5.2. Initial Source/Receptor Position Matrix

Receptor	Source 1		...	Source m

5.1.6 Calm Winds

The derivation of the straight-line Gaussian plume model given in (5.1) is defined under the assumption of a non-zero wind speeds. In the case of calm winds, there are two problems. First, there is a zero wind speed, and second, there is no direction defined. For these codes, the first problem is solved by assuming a minimum wind speed (1 m/s) for calm winds and applying the straight-line Gaussian plume model. To solve the second problem, no defined direction, the code randomly picks a direction. The code assumes an equal weighting for each direction unless the user supplies a distribution of low wind speed directions.

5.1.7 Calculation of Average and Time Integrated Concentrations

The chronic and acute model output the average and time-integrated concentrations, respectively. In the plume models, the average concentration is given by

$$c_{av}(x, y, z) = \frac{1}{T} \sum_{i=0}^{n(T)} c_i(x, y, z) W_i \qquad (5.19)$$

where $c_{av}(x,y,z)$ = the average concentration at distance x, crosswind position y, and height z (Ci/m^3)

$c_i(x,y,z)$ = the ith concentration

$n(T)$ = the number of concentrations during the time period, T

W_i = a weighting factor, which is the number of hours of the ith concentration in time period, T

For the acute model, the time-integrated concentration is given by

$$E(x, y, z) = c_i(x, y, z) \Delta t \qquad (5.20)$$

where $E(x,y,z)$ is the time-integrated concentration $(Ci\text{-}hr/m^3)$ and Δt is the time step. For this suite of codes, the time step is always 1 hour.

5.2 LAGRANGIAN PUFF MODEL

Lagrangian puff models use a sequence of puffs to simulate plumes. The use of puffs to simulate plumes permits these models to easily account for spatial and temporal variations in the atmospheric conditions that affect transport and diffusion. In addition, Lagrangian puff models provide more straight-forward treatment of multiple sources and temporal variations in source terms than do plume models. However given identical diffusion and deposition parameterizations and appropriate model input, Lagrangian puff models can exactly reproduce the results of a straight-line plume model.

Lagrangian puff models consist of two parts, a wind field model and a diffusion model. The wind field model is used to move puffs. The diffusion model describes the spread of the puffs. This section describes the major components of Lagrangian puff models, the wind field model and the diffusion model.

5.2.1 Transport

Puff movement is determined by the wind at the center of the puff, independent of the size of the puff. The wind field model implicit in the straight-line plume model assumes that the wind direction and speed do not change in time or space. Once released to the atmosphere, material moves in a straight line with a direction defined by the wind direction at the time of release. Straight-line plume models also implicitly assume that the transport speed is immaterial. Wind fields in puff models permit curved plume trajectories and explicitly consider the transport time.

The wind model used in these codes is based upon a single meteorological station. For hourly meteorological data, this provides temporal changes in the wind speed. The model assumes spatially uniform winds, except the user can supply an array of surface roughness for each grid point on the receptor grid. This would allow the wind speed to vary spatially, but the wind direction would still be spatially uniform. See Section 5.3.2 for information on how the surface roughness effects the wind speed.

The position of a puff is determined by a series of movements starting at the time the puff is released. Hourly wind fields, based on the observed wind, are used to compute the puff movement. The number of time steps used in computing the puff movement is equal to the number of puffs released per hour (NPH) and is set as an input parameter in the codes. The time step used in puff movement is then 1/NPH and is referred to as the puff advection period. An even shorter interval, called the sampling period, is used in computing the time-integrated concentrations and surface depositions.

The puff movement is computed in a five-step process. In sequence, the steps in the process are:

1.   Estimate the wind at puff transport height at the current position

2.   Make an initial estimate of puff position at the end of the advection period using the transport-height wind for the current puff position

3.   Estimate the transport-height wind at this initial estimate of the puff's position at the end of the advection period

4.   Using the winds estimated in Step 3 and the puff's current position, make a second estimate of the puff's position a the end of the advection period

5.   Average the position estimated in steps 2 and 4

The average position will be the position of the puff at the end of the advection period. These steps are described mathematically below.

The puff movement calculation begins by calculating the wind at the puff's current position. The wind components are based on the station's observed friction velocity, wind direction, and surface roughness at the puff's current position. The surface roughness of the current position is the surface roughness of the closest point on the receptor grid.

The diabatic wind profile is used to adjust calculate the wind speed at the puff-transport height from the friction velocity and surface roughness (see Section 5.3.2). In general, the transport height of the puffs will be their effective release height. The distance moved will be calculated using the wind speed for the effective release height of the puff when the effective release height is ? 10 meters and ? 100 meters. The 10-meter wind speed will be used in computing movements for puff with release heights < 12 meters, and the wind speed at 100 meters will be used to compute movements of puffs with effective release heights > 100 meters. Extrapolation of wind speeds from a height of 10 meters to heights in excess of 100 meters is not considered appropriate.

Next, an initial estimate of movement is made using the components of the transport vector at the puff's starting position. For a puff initially at x, y, z, the change in position is given by

$$\Delta x = u(x, \ y, z) \Delta t$$
$$\Delta y = v(x, \ y, z) \Delta t$$

(5.21)

where u and v are the east-west and north-south components of the wind vector, respectively, and ? t is the advection period (3600 sec/NPH). The initial estimate of the puff's position at the end of the advection period is

$$x' = x + \Delta x$$
$$y' = y + \Delta y$$

(5.22)

The transport winds at this location at the current time are then determined following the same procedure used to obtain the initial transport wind estimates.

The second set of estimates of the transport wind components is used to obtain a second estimate of the puff movement

$$\Delta x' = u(x', y', z) \Delta t$$
$$\Delta y' = v(x', y', z) \Delta t$$

(5.23)

Finally, the puff's position at the end of the advection period x", y" is determined from the current position and the average of the two movement estimates

$$x'' = x + 0.5(\Delta x + \Delta x')$$
$$y'' = y + 0.5(\Delta y + \Delta y')$$

(5.24)

Material in a puff continues to contribute to the time-integrated air concentration and surface deposition at grid nodes near the edge of the receptor grid even after the center of the puff leaves the interior of the receptor grid as long as the puff center stays within the tracking region. The tracking region is an area surrounding the receptor grid that, along with allowing the puffs to continue to contribute air concentration and deposition to the grid, also allows the puffs to return from the tracking region to the receptor grid. Once the center of the puff moves beyond the tracking region, the puff is consider to no longer be contributing to the grid and is turned off. The size of the tracking region is a fraction of the distance from the center of the receptor grid to the various boundaries (north, south, east, and west). The fraction is normally set to 0.4, but can be altered by the user. For puffs in the tracking region, the puff movement is determined by the winds at the closest grid points on the receptor grid.

5.2.2 Puff Diffusion

In Lagrangian puff models, calculation of concentrations take place in two steps. The first step is calculation of the concentration in the puff as a function of distance from the center of the puff. The second step is calculation of concentration at a fixed point in the model domain.

The concentration in puffs is given by

$$c_p(r, z, t) = \frac{Q_p(t_o, t)}{(2\pi)^{3/2} s_r^2 s_z} \exp(-\frac{r^2}{2s_r^2}) G(z)$$

(5.25)

where $c_p(r,z,t) =$ the concentration at a distance r from the enter of the puff and height z above ground at time t (Ci/m^3)

$Q_p(t_o,t) =$ the mass in the puff $(Q_p = Q'(t_o)?t)$ released at time t_o corrected for depletion and decay between t_o and t (Ci)

$s_r =$ the radial diffusion coefficient (generally assumed to be equal to s_y) (m)

$G(z) =$ The vertical factor (see Equation (5.2))

The mass in each puff is set at the time the puff is released. It is the product of the release rate and the time separation between puffs. As each puff moves through the model domain, the mass in the puff may be adjusted to account for deposition and radioactive decay.

5.2.3 Calculation Of Concentrations And Exposure

Calculation of the concentration at a point involves the summation of the contributions from all puffs. This summation is represented as

$$c_{ij}(z, t) = \sum_{p=1}^{N} c_p \left([(x_i - x_p)^2 + (y_j - y_p)^2]^{1/2}, z \right) \qquad (5.26)$$

where $?_{ij}(z,t) =$ the concentration at position i,j at height z at time t (Ci/m^3)
      $N =$ the number of puffs released prior to t
      $x_i, y_j =$ the coordinates of position i,j.

In practice the summation is limited to puffs in the immediate vicinity of the point. Immediate vicinity is defined as a function of a characteristic puff dimension, for example $4s_r$. In the codes, the immediate vicinity can be defined by the user, but by default is defined as $5.3s_r$.

For the acute model, the time-integrated concentration or exposure is required. In Lagrangian puff models the exposure is calculated as

$$E_{ij}(z, T) = \sum_{0}^{T} c_{ij}(z, t)\Delta t \qquad (5.27)$$

Exposures may also be calculated directly from puffs by including ?t in Equation (5.25).

The average concentration at a point is calculated in much the same manner as the exposure. It is

$$\overline{c_{ij}(z, t_1, t_2)} = \frac{1}{(t_2 - t_1)} \sum_{t_1}^{t_2} c_{ij}(z, t)\Delta t \qquad (5.28)$$

where t_1 and t_2 define the time period for the average.

5.2.4 Sector-Average Model

There is no Lagrangian puff model equivalent to the sector-average straight-line model.

5.2.5 Multiple Sources

Multiple sources are easily defined within the framework of Lagrangian puff models because these models use a Cartesian grid. There is no fundamental requirement that sources be placed at any specific location within the grid. After a puff is released the location of the source

is no longer relevant, although it may be useful to retain the identity of the source of each puff. As in the plume models, the acute model assumes that all sources are co-located, while the chronic model allows the sources to be placed anywhere on the grid.

5.2.6 Area Sources

Area sources may be modeled in Lagrangian puff model by using one or more sources. Simple area sources may be treated using a single source and giving puffs finite initial dimensions if the receptors of interest are outside of and not close to the area. More complex sources may be treated by dividing the area source into regions and treating each region as a simple source. This same procedure may be required for simple area sources if there are receptors of interest in or near the source area. The distance from the area source to the closest receptors can be used to develop guidelines for determining the number and configuration of sources needed for a specific application.

5.2.7 Calm Winds

Lagrangian puff models do not become undefined if the wind speed is zero - puff transport just stops. If the diffusion coefficients are defined on the basis of distance, diffusion will also stop when the wind speed becomes zero. Diffusion can be permitted to continue during calms by defining diffusion coefficients on the basis of time rather than wind speed.

5.2.8 Finite Sources

In Lagrangian puff models, finite sources are treated by assigning puffs initial dimensions. An appropriate set of dimensions can be determined from the stack flow and the time between puffs. The relative magnitudes of the horizontal and vertical diffusion coefficients must be assumed. Because this procedure gives puffs dimensions relative to real plumes, Lagrangian models probably should not be used to determine concentrations in the immediate vicinity of the stack.

5.3 MODEL COMPONENT PARAMETERIZATIONS

The preceding sections describe the basic dispersion models included in the model suite. This section describes the paramaterizations for the components included in the models.

5.3.1 Effective Release Height

Both the plume and puff models in the suite have the ability to calculate concentrations resulting from elevated releases. In each case the height of release is the effective release height. Effective release height is defined as the actual release height with corrections for plume downwash and plume rise.   Formally,

$$h_e = h_s + \Delta h_{pr} + \Delta h_{dw} \tag{5.29}$$

where h_s is the stack height, Δh_{pr} is the correction to the effective height due to plume rise, and Δh_{dw} is the correction to the effective height due to downwash. The downwash correction is a function of time (effluent vertical velocity and wind speed); the plume rise correction is a function of both time and distance from the source.

5.3.1.1 Downwash Correction

A plume downwash correction is applied in all plume rise calculations when the effluent vertical velocity at the stack exit is less than 1.5 times the wind speed at release height. This correction, which accounts for aerodynamic effects, is

$$\Delta h_{dw} = 4 r_o [\frac{w_o}{U(h_s)} - 1.5] \tag{5.30}$$

If the stack-exit vertical velocity is equal to or greater than 1.5 times the release height wind speed, the downwash correction is zero.

The correction described above is applied in all wind speeds in the EPA's Industrial Source Complex (ISC3) codes (EPA 1995). However, there is some question about the appropriateness of the correction as the stack height wind speed approaches zero. For example, Petersen and Lavadas (1986) assume a minimum release-height wind speed of 1.37 m/s when the winds are near calm. In the codes, the default minimum wind speed for calculating plume rise is 1.5 m/s, but this variable can be defined by the user.

5.3.1.2 Plume Rise

Plume rise is calculated using the methods of Briggs (1969, 1972, 1973, 1975 and 1984). The RATCHET (Ramsdell et al. 1994), ISC3 (EPA 1995), and INPUFF (Petersen and Lavdas 1986) codes use essentially the same set of equations for estimating final plume rise. These equations are implemented in the suite of codes with minor modifications. In addition for the plume models, transition plume rise equations are implemented for receptors near the source. Plume rise calculated with the transition equations is compared with plume rise calculated with final rise equations and the lesser value is used to determine the effective release height. Transition rise is not calculated in the puff model.

The primary factors entering into plume rise calculations are the inside radius of the stack, momentum and buoyancy fluxes from the stack, wind speed at release height, and atmospheric stability. The specific plume rise equation used depends on relative importance of the momentum and buoyancy fluxes, atmospheric stability (unstable/neutral and stable), wind speed, and for buoyant plumes the magnitude of the buoyant flux.

The momentum flux, F_m, is defined as

$$F_m = \frac{\boldsymbol{r}_o}{\boldsymbol{r}_a} \; w_o^2 \; r_o^2$$

$$\approx \frac{T_a}{T_o} \; w_o^2 \; r_o^2$$

(5.31)

where $?_o$ =   stack effluent density (kg/m^3)
$?_a$ =   ambient air density (kg/m^3)
w_o =   stack effluent vertical velocity (m/s)
r_o =   stack inside radius (m)
T_a =   ambient air temperature at stack height (K)
T_o =   stack effluent temperature (K).

If the release is through an uncapped vent that is not circular, the stack radius may be approximated by the cross-sectional area divided by pi. The buoyancy flux is

$$F_b = g\frac{\boldsymbol{r}_o - \boldsymbol{r}_a}{\boldsymbol{r}_a} \; w_o \; r_o^2$$

$$\approx g\frac{T_o - T_a}{T_a} \; w_o \; r_o^2$$

(5.32)

Plumes are referred to as either momentum dominated (jets) or buoyancy dominated. Very near the stack, plumes are generally momentum dominated. As rise continues, plumes tend to become buoyancy dominated unless the density of the stack effluent and the air are the same.

Momentum Rise - Unstable and Neutral Conditions. During unstable and neutral atmospheric conditions, the final plume rise, $?=h_{prf}$, for momentum-dominated plumes is

$$\Delta h_{prf} = 6 \; r_o[\frac{w_o}{U(h_s)}]$$

(5.33)

This rise is generally small and will reach its maximum value near the stack.

Buoyancy Rise - Unstable and Neutral Conditions. For buoyancy-dominated plumes in unstable and neutral conditions, the final plume rise is

$$\Delta h_{prf} = 1.6 \; F_b^{1/3} \; \frac{x_f^{2/3}}{U(h_s)}$$

(5.34)

where x_f is the distance to final plume rise. This distance is directly related to the buoyancy-flux parameter. For small sources ($F_b < 55$) the distance to final rise, in meters, is

$$x_f = 49\,F_b^{5/8} \tag{5.35}$$

and for large sources ($F_b = 55$) it is

$$x_f = 119\,F_b^{2/5} \tag{5.36}$$

Critical Temperature Difference. A critical temperature difference can be calculated for use in determining whether a plume is dominated by momentum or buoyancy. This critical temperature difference is found by combining Equations (5.33) and (5.34), setting $?T_c = (T_o - T_a)$, and solving $?T_c$. The results of these manipulations are

$$\Delta T_c = 0.0187 \ (\frac{w_o}{r_o^2})^{1/3} \ T_a \tag{5.37}$$

for small sources, and

$$\Delta T_c = 0.00456 \ (\frac{w_o^2}{r_o})^{1/3} \ T_a \tag{5.38}$$

for large sources. Note that the leading constants in these equations have dimensions. If the actual difference between the initial effluent temperature and the ambient air at stack height is less than the critical temperature difference, plume rise is dominated by momentum. Otherwise, the plume rise is buoyancy dominated.

Calm Winds. Equations (5.33) and (5.34) cannot be used to calculate plume rise in calm winds because wind speed is in the denominator in the equations. To prevent this problem, a minimum stack height wind speed is specified. This minimum wind speed is the same as that used in the downwash calculations.

Stable Conditions. During stable atmospheric conditions, plume rise calculations include an atmospheric stability parameter. The atmospheric stability parameter is defined as

$$S = \frac{g}{T_a} \ \frac{\partial q}{\partial z} \tag{5.39}$$

where g is the gravitational acceleration (~ 9.8 m/s^2) and $??/?z$ is the potential temperature lapse rate. Potential temperature lapse rates of 0.02 K/m, 0.035 K/m, and 0.05 K/m are assumed for stability classes 5, 6, and 7, respectively.

Momentum Rise - Stable Conditions. The final rise momentum-dominated plumes in stable conditions is given either by

$$\Delta h_{prf} = 1.5 \ (\frac{F_m}{U(h_s)\sqrt{S}})^{1/3} \qquad (5.40)$$

or equation (5.33), whichever is smaller. Again, momentum-dominated plume rise is generally small and reaches its maximum value near the stack.

Buoyancy Rise - Stable Conditions. The final rise of buoyancy-dominated plumes in stable conditions is

$$\Delta h_{prf} = 2.6 \ [\frac{F_b}{U(h_s) \ S}]^{1/3} \qquad (5.41)$$

This rise is assumed for all distances greater than

$$x_f = 2.0715 \ \frac{U(h_s)}{\sqrt{S}} \qquad (5.42)$$

When the wind is near calm, the final rise of buoyancy-dominated plumes in stable atmospheric conditions can be estimated using

$$\Delta h_{prf} = 4 \ F_b^{1/4} \ S^{-3/8} \qquad (5.43)$$

Equations (5.41) and (5.43) can be used to define a critical wind speed for use in selecting the appropriate equation. This wind speed is

$$U_c = 0.2746 \ (F_b\sqrt{S})^{1/4} \qquad (5.44)$$

Equation (5.41) is used to calculate final plume rise when the wind speed at stack height is greater than the critical speed. Otherwise, the final plume rise is calculated by Equation (5.43). Typically, the critical wind speed is less than 1 m/s.

Critical Temperature Difference. The critical temperature difference for determining whether a plume is dominated by momentum or buoyancy is determined using Equations (5.40) and (5.41). Assuming that the wind speed is greater that U_c, the critical temperature difference is

$$\Delta T_c = 0.01958 \ w_o \ S^{1/2} \ T_a \tag{5.45}$$

Equations (5.40) and (5.43) can be used to estimate a critical temperature difference during calm, stable conditions. This difference is

$$\Delta T_c = 0.0138 \ w_o \ S^{1/2} \ T_a \tag{5.46}$$

Except for the value of the leading coefficient, Equations (5.45) and (5.46) are identical. Equation (5.45) gives the larger critical temperature of the two equations. Therefore, the suite of codes only uses Equation (5.45).

Elevated Inversions. Briggs (1975, 1984) discuss the effect of elevated inversion on plume rise. The equations provided in these discussions include parameters related to the strength of the inversion that would be difficult to estimate from routine meteorological data. In the suite of codes, the plumes are assumed to be bent-over and are confined to the mixing layer initially unless released above the mixing layer because, according to Briggs (1984), they have limited ability to penetrate inversions.

Transition Plume Rise. Only in the plume models are the transition plume rise equations used to determine plume rise for dispersion calculations for receptors that are near the source. During the transition phase, plume rise is independent of atmospheric stability. The transition rise equation for jets is

$$\Delta h_{prt} = (\frac{3 \ F_m \ x}{\boldsymbol{b}_m^2 \ U^2})^{1/3} \tag{5.47}$$

where ß$_m$ is an entrainment constant for jets. The entrainment constant for jets given by Briggs (1975, 1984) is

$$\boldsymbol{b} = 0.4 + \frac{1.2 \ U}{w_o} \tag{5.48}$$

The transition rise for buoyant plumes is given by

$$\Delta h_{prt} = (\frac{3 \ F_m}{\boldsymbol{b}_m^2 U^2} x + \frac{3}{2 \ \boldsymbol{b}_b^2} \ \frac{F_b}{U^3} x^2)^{1/3} \tag{5.49}$$

where ß$_b$ is the entrainment factor for buoyant plumes. Briggs (1984) suggest a value of 0.6 be used for ß$_b$.

Within a few meters of the source the momentum term may dominate the transition plume rise. However, generally the buoyancy term will be dominant at distances of 100 m or

more. At these distances the momentum term may be dropped and Equation (49) may be simplified to

$$\Delta h_{prt} = \frac{1.6 \ F_b^{1/3} \ x^{2/3}}{U} \tag{5.50}$$

Whenever transition plume rise is calculated in the codes, the transition rise is compared with the final plume rise. The lesser plume rise is used in dispersion calculations.

In the case where the Schulman and Scire building downwash model is being used, the transitional rise associated with this model is used instead of the above transitional rise equations. The transition rise equation for Schulman and Scire downwash model is given in Section 5.3.4.1.

5.2.3   Wind Profile

Frequently, wind speeds at heights other than the height at which they were measured are required by the atmospheric models. Many wind measurements are made at 10 meters above the ground or lower. For elevated releases, measured winds at these heights are not available. Thus, the models must estimate them from the surface-wind data. For both the puff and plume model, if the release height is below 12 meters, the wind speed at 10 meter is used.

A diabatic wind-profile model is used to adjust the wind speed as needed. No attempt is made to model the variation of wind direction with height above the ground. Diabatic profiles account for the effect of surface roughness and atmospheric stability on the variation of wind speed with height.

The diabatic profile model is derived from the atmospheric boundary layer similarity theory proposed by Monin and Obukhov (1954). The basic hypothesis of similarity theory is that a number of parameters in the atmospheric layer near the ground, including the wind profiles, should be universal functions of the friction velocity, a length scale, and the height above ground. The length scale, L, is referred to as the Monin-Obukhov length and the ratio z/L is related to atmospheric stability. When z/L is negative and large (e.g., < -2), the atmosphere is extremely unstable (convective). When z/L is near zero, the atmosphere is neutral, and when it is positive and large (e.g., > 1), the atmosphere is extremely stable. A large body of experimental data supports Monin-Obukhov similarity theory.

The diabatic wind profile is

$$U(z) = \frac{u_*}{k} [\ln(\frac{z}{z_0}) - \psi(\frac{z}{L})] \tag{5.51}$$

where $U(z)$ =   wind speed at height z (m/s)

u$_*$	=	friction velocity (boundary-layer turbulence scaling velocity) (m/s)
k	=	von Karman constant, which has a value of about 0.4 (no units)
z	=	height (m)
z$_0$	=	measure of local surface roughness (roughness length) (m)
?	=	stability correction factor
L	=	Monin-Obukhov Length (m)

The term ?(z/L) accounts for the effects of stability of the wind profile. In stable atmospheric conditions, ?(z/L) has the form -az/L, where a is a value between 4.7 and 5.2. For the models, a value of 5 is used for a. In neutral conditions ?(z/L) is zero, and the diabatic profile simplifies to a logarithmic profile.

In unstable air, ?(z/L) is more complicated. According to Panfosky and Dutton (1984), the most common form of ?(z/L) for unstable conditions is based on the work by Businger et al. (1971) and Paulson (1970). It is

$$\boldsymbol{y}(\frac{z}{L}) = \ln([\frac{1+x^2}{2}][\frac{1+x}{2}]^2) - 2\tan^{-1}x + \frac{\boldsymbol{p}}{2} \tag{5.52}$$

where x = (1- 16z/L)$^{1/4}$. Equation (5.51) is used to estimate the friction velocity (u$_*$) from wind speed, surface roughness, and the Monin Obukhov Length. In unstable and neutral conditions, the use of Equation (5.51) is limited to the lowest 100 meters of the atmosphere. In stable conditions, the upper limit of application of Equation (5.51) is the smaller of 100 meters or three times the Monin-Obukhov length. Skibin and Businger (1985) provide the rationale for limiting application of Equation (5.52) to three times the Monin-Obukhov length in stable conditions.

The Monin-Obukhov length is a measure atmospheric stability. It varies from small negative values (a few meters) in extremely unstable atmospheric conditions to negative infinity as the atmospheric stability approaches neutral from unstable. In extremely stable conditions, the Monin-Obukhov length is small and positive. As neutral conditions are approached from stable conditions, the Monin-Obukhov length approaches infinity. Thus, there is a discontinuity in the Monin-Obukhov length at neutral. However, this discontinuity is not a problem because the Monin-Obukhov length is found in the denominator of expressions.

Golder (1972) provides a means for converting from stability class estimates to Monin-Obukhov lengths. Figure 5.1, derived from Golder (1972, Figure 5), shows the range for 1/L as a function of stability classes and surface roughness. Mid-range values for 1/L from this figure are used by the model to estimate 1/L.
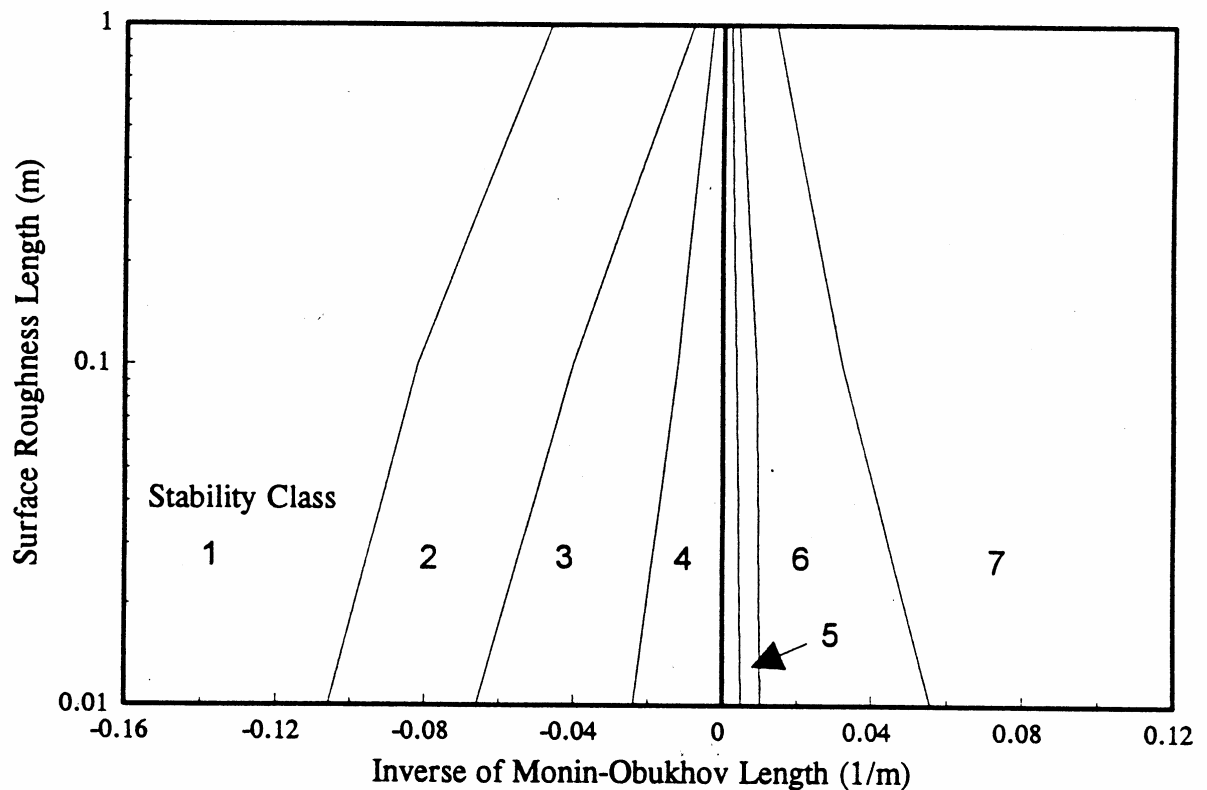

Figure 5.1. Relationship between Stability Class and Monin-Obukhov Length as a Function of Surface Roughness Length

5.3.3 Diffusion Coefficients

The spread of effluents in plumes and puffs is described by diffusion coefficients. In Gaussian models these coefficients are standard deviations of the concentration distributions. Theoretically, these coefficients are related to atmospheric turbulence and the time since release.

In practice many schemes are used to estimate diffusion coefficients. Historically, most of the schemes have been based on atmospheric stability classes and distance from the source. More modern schemes use information on atmospheric turbulence and time since release.

The suite of codes includes several schemes for calculating diffusion coefficients. The user selects the scheme of their choice.   The schemes included in the code suite are the following.

Briggs Open-Country Conditions

The Briggs "open country" curves (Briggs 1973) are based on combining the Pasquill (Pasquill 1961), BNL (Smith 1961), and TVA (Carpenter et al. 1971) curves, using theoretical

concepts regarding the asymptotic limits of the formula. The curves are discussed by several authors, including Gifford (1976) and Hanna et al. (1982).   Table 5.4 shows the various diffusion coefficient equations as a function of atmospheric stability.

Briggs Urban Conditions

The Brigg's Urban Condition curves (Briggs 1973) are based on the diffusion experiment in St. Louis (McElroy and Pooler 1968). Table 5.5 presents the Briggs Urban Condition equations as a function of atmospheric stability.

Table 5.4. Briggs Open Country Conditions Diffusion Coefficients Formula (where x is in meters)

Stability Class	$?_y$ (m)	$?_z$ (m)
A	$0.22x(1 + 0.0001x)^{-\frac{1}{2}}$	$0.20x$
B	$0.16x(1 + 0.0001x)^{-\frac{1}{2}}$	$0.12x$
C	$0.11x(1 + 0.0001x)^{-\frac{1}{2}}$	$0.08x(1 + 0.0002x)^{-\frac{1}{2}}$
D	$0.08x(1 + 0.0001x)^{-\frac{1}{2}}$	$0.06x(1 + 0.0015x)^{-\frac{1}{2}}$
E	$0.06x(1 + 0.0001x)^{-\frac{1}{2}}$	$0.03x(1 + 0.0003x)^{-1}$
F	$0.04x(1 + 0.0001x)^{-\frac{1}{2}}$	$0.016x(1 + 0.0003x)^{-1}$

Table 5.5 Briggs Urban Condition Diffusion Coefficient Formulas (where x is in meters)

Stability Class	$?_y$ (m)	$?_z$ (m)
A-B	$0.32x(1 + 0.0004x)^{-\frac{1}{2}}$	$0.24x(1 + 0.001x)^{\frac{1}{2}}$
C	$0.22x(1 + 0.0004x)^{-\frac{1}{2}}$	$0.20x$

Pasquill-Gifford (ISC3)

The Pasquill-Gifford (ISC3) equations are an approximate fit to the Pasquill-Gifford curves (Turner, 1970) as described in the User's Guide for the Industrial Source Complex (ISC3) Model, Volume II (EPA 1995) assuming rural conditions. For urban conditions, the equation used in the ISC3 model for the diffusion coefficients are the same as the Briggs Urban Condition equations. The equation used to calculate the horizontal diffusion coefficient is (with the downwind distance in kilometers):

$$\boldsymbol{s}_y = 465.11628(x)\tan(TH) \tag{5.53}$$

where

$$TH = 0.017453293[c - d\ln(x)] \tag{5.54}$$

The coefficients c and d are dependent upon atmospheric stability and are given in Table 5.6. The vertical diffusion coefficient is calculated using:

$$\boldsymbol{s}_z = a\,x^b \tag{5.55}$$

where the coefficients a and b depend upon downwind distance, x (in kilometers), and atmospheric stability. The coefficients a and b are given in Table 5.7.

Pasquill-Gifford (NRC)

The diffusion coefficient equations for the Pasquill-Gifford (NRC) implementation are the diffusion coefficients that have been attributed to Eimutis and Konieck (1972). These diffusion coefficient equations have been used in past Nuclear Regulatory Commission diffusion models (MESODIF-II [Powell et al. 1979], XOQDOQ [Sagendorf et al. 1982], PAVAN [Bander 1982], and MESORAD [Ramsdell and Athey. 1981]). The basic equation is

$$s_j = A_j x^{B_j} + C_j \qquad (5.56)$$

for j = y: $B_y = 0.9031$, $C_y = 0$. The other constants are given in Table 5.8.

<u>Turbulent Statistics</u>

The best representation of the diffusion coefficients should be estimated from directly from statistics for atmospheric turbulence. Often, measured turbulence statistics are not available, but may be estimated from atmospheric conditions (e.g., wind speed, atmospheric stability, and surface roughness).

The equation generally recommended for estimating horizontal diffusion coefficients near the source is

$$s_y = s_v t f_y(t) \qquad\qquad (5.57)$$

where s_y =   horizontal diffusion coefficient (m)

      s_v =   standard deviation of the component of the wind perpendicular to the mean direction (m/s)

      t =   travel time (s)

      $f_y(t)$ =   nondimensional function related to the travel time and turbulence time scale.

Irwin (1983) recommends that the function $f_y(t)$ be computed using

$$f_y(t) = [1 + 0.9(\frac{t}{T_i})^{1/2}]^{-1}$$ (5.58)

where T_i is the turbulence time scale, which has a value of about 1000 s.

For the puff models, a less complex algorithm for horizontal diffusion has been implemented. For the first hour following a release, the horizontal diffusion coefficient is a function of atmospheric turbulence and time as indicated in

$$\boldsymbol{s}_y = 0.5 \boldsymbol{s}_v t$$ (5.59)

where the coefficient is the approximate value of $f_y(t)$ defined in equation (5.58) for t = 1800 s (30 minutes). After the first hour, diffusion is a function of t, as shown by

$$\boldsymbol{s}_y = c_{sy} t$$ (5.60)

where c_{sy} is a proportionality constant with units of meters per second and, as a default, set to 0.5.

In the puff model, the actual calculation of s_y is done in increments to avoid problems associated with spatial and temporal changes in conditions. The equations implemented in the code are

$$\boldsymbol{s}_y(t + \Delta t) = \boldsymbol{s}_y + 0.5 \boldsymbol{s}_v \Delta t$$ (5.61)

for the first hour, and

$$\boldsymbol{s}_y(t + \Delta t) = \boldsymbol{s}_y + c_{sy} \Delta t$$ (5.62)

The vertical diffusion coefficients are estimated by using an equation similar to equation (5.58), with s_z replacing s_y, s_w replacing s_v, and $f_z(t)$ replacing $f_y(t)$, respectively. It is

$$\boldsymbol{s}_z = \boldsymbol{s}_w t f_z(t)$$ (5.63)

Two forms for the nondimensional function $f_z(t)$ are used by Petersen and Lavdas (1986). These are, for unstable and neutral conditions,

$$f_z(t) = 1$$ (5.64)

and ,for stable conditions and above the mixing layer,

$$f_z(t) = [1 + 0.9(\frac{t}{T_i})^{1/2}]^{-1}$$ (5.65)

where $T_i = 50$ s.

As with the horizontal diffusion coefficient when the vertical diffusion is calculated in the puff model, the vertical diffusion coefficient is not computed directly from Equation (5.63), but is computed from the time derivatives of these equations.

The turbulence parameters, s_v and s_w, are estimated using atmospheric boundary layer relationships. The relationship under stable and neutral conditions are those given by Hanna et al. (1982) relating the turbulence parameters to friction velocity, u_* (See Section 5.3.2), and other atmospheric boundary layer parameters. The expression for stable atmospheric conditions is

$$s_v = s_w = u_* 1.3 (1 - \frac{z_p}{H})$$ (5.66)

where z_p is the puff transport height and is below 0.9H (H is the mixing height). Above 0.9H,

$$s_v = s_w = 1.3 u$$ (5.67)

For neutral conditions throughout the entire depth of the mixing layer, the expression used is

$$s_v = s_w = u_* 1.3 \exp(-2\frac{fz_p}{u_*})$$ (5.68)

where f is the coriolis parameter and assumed to be 1.1E-4. Equation (5.67) is used above the mixing layer in neutral conditions.

For unstable conditions, the relationships are given by Hanna et al. (1982) for s_v. It is

$$s_v = u_* (12 - \frac{0.5 H}{L})^{1/3}$$ (5.69)

where L is the Monin-Obukhov Length (see Section 5.3.2).

Three expressions are used to estimate s_w in unstable conditions. If the puff transport height is in the lower half of the mixing layer, it is computed from

$$s_w = 1.3\,u_*(1 - \frac{3\,z_p}{L})^{1/3} \qquad\qquad (5.70)$$

and if the effective transport height is in the upper half of the mixing layer, it is computed from

$$s_w = 1.3\,u_*(1 - \frac{1.5\,H}{L})^{1/3} \qquad\qquad (5.71)$$

The first of these relationships was proposed by Panofsky et al. (1977). The second follows from the first if it is assumed that s_w is independent of height from z_p between 0.5H and H. Above the mixing layer it is assumed that the atmosphere is stable. Thus, s_v and s_w are both computed using Equation (5.67).

Ultimately, a lower bound of 0.01 m/s is used for both s_v and s_w. This lower bound is applied for all heights and stabilities.

Distance-Based Coefficient in Puff Model

In the puff models, the diffusion coefficients that are based on distance (e.g., Briggs Open Country, Pasquill-Gifford - NRC) are calculated using an iterative method for each time step. First, the distance associated with the previous time step's diffusion coefficient is determined. For the current time step, the additional distance (wind speed multiplied by time) traveled is calculated. The two distances are added to obtain the new distance from which the coefficients are calculated.

5.3.4 Diffusion Coefficient Corrections

Atmospheric dispersion in the vicinity of buildings is generally treated by modifying the diffusion coefficients used in the straight-line Gaussian plume model [Equation (5.1)]. The modified diffusion coefficients are denoted by s_y and s_z rather than s_y and s_z. Several methods of calculating s_y and s_z have been proposed. The suite of codes includes several options for calculating s_y and s_z. These corrections are not applicable to the puff model.

5.3.4.1 Building Wakes and Low Wind Speed Meander

There are two different models for building wake, the model based on the work by Ramsdell and Fosmire (1995, 1998a, 1998b) and those used in the EPA's ISC3 model (1995). The Ramsdell and Fosmire model also includes a diffusion coefficient correction for low wind speed meander that is separate from building wakes. The two different models are described in the following sections.

Ramsdell and Fosmire Model

Ramsdell and Fosmire (1995,1998a, 1998b) suggest that the maximum concentration in the vicinity of a building can be calculated using

$$\Sigma_y^2 = (s_y^2 + \Delta s_y 1^2 + \Delta s_y 2^2)^{1/2} \tag{5.72}$$

where s_y is the usual diffusion coefficient, $?s_{y1}$ is a low wind speed correction, and $?s_{y2}$ is a high wind speed, wake correction. An identical relationship defines s_z. The low-speed corrections are given by

$$\Delta s_y 1^2 = A_y \left[\ 1 - (1 + \frac{x}{1000\ U}) \exp(- \frac{x}{1000\ U}) \right]$$

$$\Delta s_z 1^2 = A_z \left[\ 1 - (1 + \frac{x}{100\ U}) \exp(- \frac{x}{100\ U}) \right] \tag{5.73}$$

where A_y and A_z are constants that depend, in part, on the parameterization used for the normal diffusion coefficients. Table 5.9 contains the constants A_y and A_z for the various diffusion coefficient parameterization schemes.

The high speed wake corrections are given by

$$\Delta s_y 2^2 = B_y \ U^2 A \ [1 - (1 + \frac{x}{10\sqrt{A}} \ \exp(- \frac{x}{10\sqrt{A}})$$

$$\Delta s_z 2^2 = B_z \ U^2 A \ [1 - (1 + \frac{x}{10\ \sqrt{A}} \ \exp(- \frac{x}{10\sqrt{A}}) \tag{5.74}$$

where B_y and B_z are constants that depend, in part, on the parameterization chosen for the normal diffusion coefficients and A is the cross-sectional area of the building. In Ramsdell and Fosmire (1998b), it was determined that current open-terrain dispersion parameters already overestimated diffusion in high wind speed conditions. Thus, the constants B_y and B_z are zero for the various dispersion parameterizations used in these codes.

a.   Source: Ramsdell and Fosmire (1998b)

EPA's ISC3 Wake Models

As an alternative to the Ramsdell and Fosmire models, the two plume models allow the user to use the building wake models found in the EPA ISC3 model. The full details of the building wake model can be found in User's Guide for the Industrial Source Complex (ISC3) Model, Volume II (EPA 1995) and are summarized here.

The ISC3 model uses two different procedures to account for building wake. The first procedure is based on the work of Huber (1977) and Huber and Snyder (1976), and will be referred to as the Huber-Synder building wake. The other procedure follows the suggestions of Schulman and Hanna (1986) based on the work by Scire and Schulman (1980) and will be referred to as the Schulman-Scire building wake. The Schulman-Scire building wake is applied when the stack height is less than the building height plus half the lesser of the building height or width. Otherwise, the Huber-Synder building wake procedure is used. For both procedures, direction-specific building dimension are specified by the user.

Huber - Synder Building Wake

The Huber-Synder building wake procedure is calculated by using a series of steps. The first step is to calculate the transitional plume rise due to momentum (Equation 5.47) at a distance of two building heights. If the effective plume height (with no stack-tip downwash adjustment) is greater than either 2.5 building heights or the sum of the building height and 1.5 times the building width, the plume is assumed to be unaffected by the building wake. Otherwise, the plume is assumed to be affected by the building wake.

If the plume is affect by the building make, the dispersion coefficients are modified. If the ratio of the plume height to the building height is less than or equal to 1.2, both dispersion coefficients, s_y and s_z, are modified. Otherwise, only the vertical dispersion coefficient, $? s_z$, is modified. The same plume height used to determine if the plume is affect by the building wake is used in the ratio.

How the dispersion coefficients are modified depends on the shape of the building. A building can be defined as either squat (width greater than or equal to the height) or tall (height greater than the width). Dispersion coefficient are only modified if the distance from the source to receptor is greater than 3 building heights. Distances shorter than 3 building heights are assumed to be in the building cavity region and the equations are not applicable. In the codes, the concentration is set to zero if the distance is less than 3 building heights (widths) from the source.

The modified vertical dispersion coefficient for a squat or building is given by

$$
\begin{aligned}
s_{z'} &= 0.7 h_b + 0.067(x - 3 h_b) \quad \text{for } 3 h_b \leq x < 10 h_b \\
&= s_z(x + x_z) \qquad\qquad \text{for } x \geq 10 h_b
\end{aligned}
\tag{5.75}
$$

where h_b is the building height and x_z is calculated by solving the two equations at $x = 10 h_b$. For tall buildings, the same equations is used except h_b is replaced by h_w or

$$
\begin{aligned}
s_{z'} &= 0.7 h_w + 0.067(x - 3 h_w) \quad \text{for } 3 h_w \leq x < 10 h_w \\
&= s_z(x + x_z) \qquad\qquad \text{for } x \geq 10 h_w
\end{aligned}
\tag{5.76}
$$

For both tall and squat buildings, $s_{z'}$ is not permitted to be less than the unmodified s_z for distance x.

The modified horizontal dispersion coefficient for a squat building with the building width to building height ratio less than or equal to 5 or a tall building is given by

$$
\begin{aligned}
s_{y'} &= 0.35 h_w + 0.067(x - 3 h_w) \quad \text{for } 3 h_w \leq x < 10 h_w \\
&= s_y(x + x_z) \qquad\qquad \text{for } x \geq 10 h_w
\end{aligned}
\tag{5.77}
$$

where h_w is the building width.

For a building that is much wider than it is tall (width to height is greater than 5), not enough data was been collected to provide general equations for s_y. For a stack located towards the center of the building, only the height scale is considered to be significant. The modified horizontal coefficient is the same as Equation (5.77) except h_w is replaced by h_b or

$$\boldsymbol{s}_{y'} = 0.35\,h_b + 0.067(x - 3\,h_b) \quad \text{for } 3\,h_b \le x < 10\,h_b$$
$$= \boldsymbol{s}_y(x + x_z) \qquad\qquad \text{for } x \ge 10\,h_b \tag{5.78}$$

If the stack is located within about 2.5 building heights from the end of the building, the horizontal dispersion coefficient is calculated using

$$\boldsymbol{s}_{y'} = 1.75\,h_b + 0.067(x - 3\,h_b) \quad \text{for } 3\,h_b \le x < 10\,h_b$$
$$= \boldsymbol{s}_y(x + x_z) \qquad\qquad \text{for } x \ge 10\,h_b \tag{5.79}$$

The upper bound of the concentration for a squat building with a width to height ratio greater than 5 is given by Equation (5.78), while the lower bound is given by Equation (5.79). The user is given the option to use either the equation that gives the upper or lower bound concentration. By default, the upper bound is used.

Schulman-Scire Building Wake

The Schulman-Scire building wake procedure involves two steps. First, the plume is reduced due to initial plume dilution, and second, the vertical dispersion coefficient is modified. The vertical dispersion coefficient is calculated using either Equation (5.75) or Equation (5.76) depending upon the building dimensions. In addition, a linear decay factor is applied where

$$\boldsymbol{s}_{z'} = A\,\boldsymbol{s}_{z'} \tag{5.80}$$

where s_z' is from either Equation (5.75) or (5.76) and A is the linear decay factor determined by

$$A = 1 \qquad\qquad \text{if } h_e \le h_b$$
$$A = \frac{h_b - h_e}{2\,L_b} + 1 \quad \text{if } h_b < h_e \le h_b + 2\,L_b \tag{5.81}$$
$$A = 0 \qquad\qquad \text{if } h_e > h_b + 2\,L_b$$

where h_e is the height of the plume with transitional momentum rise at 2 building heights downwind.

The plume rise is estimated as follows. The initial dimensions of the downwash plume are approximated by a line source of length L_y and a depth $2R_o$ where

$$R_0 = \sqrt{2}\,A\,\boldsymbol{s}_z \qquad x = 3L_b$$
$$L_y = \sqrt{2\boldsymbol{p}}\,(\boldsymbol{s}_y - \boldsymbol{s}_z) \quad x = 3L_b, \boldsymbol{s}_y \ge \boldsymbol{s}_z \tag{5.82}$$
$$L_y = 0 \qquad\qquad x = 3L_b, \boldsymbol{s}_y < \boldsymbol{s}_z$$

where L_b is the minimum of the building height and building width and A is a linear decay factor given by Equation (5.81). Both s_y and s_z are evaluated at $x = 3L_b$, and are taken as the larger of

the building enhanced sigmas and the uncorrected sigmas. The value of s_z used in the calculation of L_y also includes the linear decay term, A (see Equation [5.80]).

The rise of a downwashed finite line source was solved in the BLP model (Schulman and Scire 1980). The neutral distance-dependent rise (Z) is given by

$$Z^3 + (\frac{3L_y}{pb} + \frac{3R_0}{b})Z^2 + (\frac{6R_0 L_y}{p\,b^2} + \frac{3R_0^2}{b^2})Z = \frac{3F_b x^2}{2\,b^2 u^3} + \frac{3F_m x}{b_j^2 u^2} \qquad (5.83)$$

The stable distance-dependent rise is calculated by

$$Z^3 + (\frac{3L_y}{pb} + \frac{3R_0}{b})Z^2 + (\frac{6R_0 L_y}{p\,b^2} + \frac{3R_0^2}{b^2})Z = \frac{3F_b x^2}{2\,b^2 u^3} + \frac{3F_m \sin(\frac{x\sqrt{s}}{u})}{b_j^2 u \sqrt{s}} \qquad (5.84)$$

with a maximum stable buoyant rise given by

$$Z^3 + (\frac{3L_y}{pb} + \frac{3R_0}{b})Z^2 + (\frac{6R_0 L_y}{p\,b^2} + \frac{3R_0^2}{b^2})Z = \frac{6F_b}{b^2 us} \qquad (5.85)$$

where

F_b	=	buoyancy flux term (Equation 5.32) (m^4/s^3)
F_m	=	momentum flux term (Equation 5.31) (m^4/s^2)
x	=	downwind distance (m)
u	=	wind speed at release height (m/s)
ß	=	entrainment coefficient (=0.6)
$ß_j$	=	jet entrainment coefficient (= $1/3 + u/w_0$, where w_0 is the stack exit velocity in m/s)
s	=	stability parameter (Equation 5.39) ($1/s^2$)

The larger of the momentum and buoyant rise, determined separately by alternately setting F_b and $F_m = 0$ and solving for Z, is selected for plume height calculations for Schulman-Scire building wake procedure. In these codes, Z is solved directly assuming the real root is the solution of interest. It should be noted that during unstable conditions, the neutral distance-dependent rise is used. For stable conditions the neutral and stable solutions are compared and the smaller of the two is used.

5.3.4.2 Buoyancy Induced Diffusion

Buoyancy induced diffusion is the correction to the initial dispersion to account turbulent motions and the subsequent entrainment of ambient air during the plume rise. Using the methods

of Pasquill and Smith (1983), the effective vertical dispersion corrected for buoyancy induced dispersion is

$$\mathbf{s}_{ze} = \sqrt{\mathbf{s}_z^2 + (\frac{\Delta h}{3.5})^2} \qquad (5.86)$$

where Δh is the plume rise and s_z is the vertical dispersion due to ambient turbulence. The horizontal dispersion is parameterized using a similar equation:

$$\mathbf{s}_{ye} = \sqrt{\mathbf{s}_y^2 + (\frac{\Delta h}{3.5})^2} \qquad (5.87)$$

where s_y is the horizontal dispersion due to ambient turbulence.

Noble gases are inert. The literature contains some discussion of solubility of noble gases that might lead to deposition on wet surfaces. This deposition is not considered to be significant for dose calculations. As a result, it is assumed that they do not deposit. Therefore, the deposition velocity for noble gases is defined to be zero.

Dry deposition velocities have been calculated from experimental data for particles and gases. In general, the deposition velocities observed for any particular material have a wide range of values. Nevertheless, the deposition velocity is frequently assumed to be constant. More realistically, the dry deposition velocity may be modeled using an analogy to electrical resistance. Resistances are associated with atmospheric conditions, physical and chemical characteristics of the material, and the physical, chemical and biological properties of the surface. Seinfeld (1986) describes the resistance analogy.

For small particles (~ 1 μ) and gases the resistance model for dry deposition velocities is

$$v_{dd} = (r_a + r_s + r_t)^{-1} \tag{5.89}$$

where r_a =   aerodynamic resistance (s/m)
r_s =   surface resistance (s/m)
r_t =   transfer resistance (s/m).

The aerodynamic and surface resistances are generally calculated from near surface wind data. In contrast, the transfer resistance is generally a function of the depositing surface. For example, transfer resistances have been associated with the stomatal openings of plant leaves (Wesley and Hicks 1977).

The aerodynamic resistance is calculated directly from the wind speed and a parameter that is characteristic of the turbulence in the lowest layer of the atmosphere. The usual parameterization for the aerodynamic resistance is

$$r_a = U(z) / u_*^{2} \tag{5.90}$$

where z   =   the height at which the concentration is estimated
u_* =   the characteristic turbulence velocity, called the friction velocity.
U(z)   =   wind speed at height z

The concentration is approximately constant for $z < 0.2 s_z$ as long as x is sufficiently large that s_z is greater than or equal to the height of release. Thus, for most elevated release cases, the 10 m wind speed may be used directly in calculating r_a.

The surface resistance is only a function of the friction velocity. It is

$$r_s = 2.6 / (0.4 \, u_*) = 6.5 / u_* \tag{5.91}$$

where 2.6 is a dimensionless empirical constant and 0.4 is von Karman's constant.

The transfer resistance is used as a mathematical device to establish an upper limit on the deposition velocity. The user can enter transfer resistance, but as a default, 10 and 100 s/m are assumed for gas (iodine) and particles, respectively.

Equation (5.88) is appropriate for small particles where the settling velocity of the particles may be neglected. A gravitational settling term should be added for larger particles when the settling velocity is not negligible. In this case, the deposition velocity is

$$v_{dd} = (r_a + r_s + r_t + r_a r_s v_s)^{-1} + v_s \tag{5.92}$$

where v_s is the gravitational settling velocity, which is a function of particle size and density. The settling velocity used in the codes is the same as that for the EPA ISC3 model (EPA 1995) and is given by

$$v_s = \frac{(r - r_{AIR}) \, g \, d_p^2 \, c_2 \, S_{CF}}{18 m} \tag{5.93}$$

where
r	$=$	the particle density (g/cm^3)
r_{AIR}	$=$	the air density (= 1.2 x 10^{-3} g/cm^3)
d_p	$=$	the particle diameter (? m)
μ	$=$	the absolute viscosity of air (=1.81 x 10^{-4} g/cm/s)
c_2	$=$	air units conversion constant (=1 x 10^{-8} cm^2/? m^2)
S_{CF}	$=$	the slip correction factor, which is computed as

$$S_{CF} = 1 + \frac{2 x_2 (a_1 + a_2 \exp(-\frac{a_3 d_p}{x_2}))}{10^{-4} d_p} \tag{5.94}$$

where x_2, a_1, a_2, and a_3 are constants with values of 6.5x10^{-6}, 1.257, 0.4, and 0.55x10^{-4}, respectively.

5.3.5.2 Wet Deposition

Wet deposition of gases is treated the same as dry deposition in Equation (5.88) with $?2_{ij}$ replacing $?1_{ij}$ and v_{dw}, a wet deposition velocity, replacing v_{dd}. The model used assumes that the exchange of gas between the air and precipitation is sufficiently rapid that an equilibrium is maintained between the concentrations in the air and in the precipitation. With this assumption, the flux of gas to the surface is proportional to the concentration of the gas in the air at ground level, the precipitation rate, and a solubility coefficient related to the Henry's law constant for

the gas. A wet deposition velocity, similar to the dry deposition velocity, combines the precipitation rate and solubility coefficient. It is

$$v_{dw} = c \ S \ P_r \qquad (5.95)$$

where S   =   the solubility coefficient
       P_r =   the precipitation rate in mm/hr
       c   =   a conversion factor to convert P_r to m/s.

The wet deposition model for gases assumes that the gases are dissolved rapidly by the precipitation. Implicit in this assumption is the assumption that the precipitation is liquid or at least has a liquid exterior because the rate of exchange of gases between air and ice is sufficiently low to be negligible. As a result, the wet deposition velocity for snow is zero if temperature data are available and the temperature is less than -3°C. If temperature data are not available, the wet deposition velocity is zero for all forms of frozen precipitation.

The wet deposition of particles is modeled using a washout coefficient. This model assumes that the particles are collected by impaction as the precipitation falls through the plume. The model also assumes that the scavenging process is irreversible, i.e. once collected the particles remain with the precipitation. The general model for wet deposition of particles is

$$w3_{ij}(t) = \Lambda \int_0^\infty c_{ij}(z, t)dz \qquad (5.96)$$

where ? is the washout coefficient. Washout coefficients are assumed to be functions of the type of precipitation (liquid or frozen), the precipitation rate, and the collection efficiency of the precipitation.

For liquid precipitation (rain, drizzle, etc), henceforth referred to as rain, the washout coefficient is calculated by the expression discussed in Slinn (1984), which is

$$\Lambda_r = \frac{C E P_r}{0.35 \ P_n^{1/4}} \qquad (5.97)$$

where $?_r$ =   the washout coefficient for rain
       C   =   empirical constant with value of 0.5
       E   =   average collection efficiency, assumed to be 1.0
       P_r =   precipitation rate in mm/hr
       P_n =   normalized precipitation rate (P_r / 1 mm/hr).

During period of frozen precipitation (snow, hail), henceforth referred to as snow, the washout coefficient will be calculated by

$$\Lambda_s = 0.2 \, P_r \qquad\qquad (5.98)$$

where $?_s$ =   the washout coefficient for snow
       0.2   =   empirical constant with units of mm^{-1}
       P_r =   the precipitation rate in mm/hr, liquid water equivalent.

The integral in Equation (5.96) can be solved based on equations used to calculate the concentration, as only the reflection term, G(z), is dependent upon z. If only the first terms of the reflection terms are used, the wet deposition of particles can be estimated as follows.

The sector averaged point and area source for the plume is given by

$$w_3 = \frac{\Lambda Q'}{U q_w} \qquad\qquad (5.99)$$

The non-sector averaged point source for a plume is given by

$$w_3 = \frac{\Lambda Q' \exp[-0.5(\frac{y}{s_y})^2]}{\sqrt{2p} \, U s_y} \qquad\qquad (5.100)$$

The non-sector averaged area source for a plume is given by

$$w_3 = \frac{\Lambda Q' 0.5 [\mathrm{erf}(\frac{a+y}{\sqrt{2} s_y}) + \mathrm{erf}(\frac{a-y}{\sqrt{2} s_y})]}{U} \qquad\qquad (5.101)$$

In the puff model, the washout is calculated by

$$w_3 = \frac{\Lambda Q \exp[-0.5(\frac{r}{s_r})^2]}{2p s_r} \qquad\qquad (5.102)$$

where Q' is the release rate corrected for depletetion and decay and Q is the mass of the puff.

5.3.5.3 Total Deposition

Given the dry and wet deposition velocities, the surface contamination that accumulated at any point during the short period is computed as

$$D(x, y, T) = \sum_0^T [w1_{ij}(t) + w2_{ij}(t) + w3_{ij}(t)]\Delta t \tag{5.103}$$

where $D(x,y,T)$ is the total surface contamination (Ci/m^2) at position (x,y) and for time period T. The deposition rate, which is calculated in the chronic models, is given by

$$D'(x, y, T) = \frac{1}{T} D(x, y, T) \tag{5.104}$$

5.3.6. Radioactive Decay

Both the plume and puff models have been developed to handle in-transit decay. The decay is based on the general algorithm for radioactive decay with branching found in Strenge (1997). The general solution is given by

$$Q_i(t) = \lambda_{ri} \sum_{n=1}^i K_{in} e^{-\lambda_{en} t} \tag{5.105}$$

where $Q_i(t)$ = activity of chain member i at time t
λ_{ri} = radioactive transition rate constant (half-life) for chain member i (s^{-1})
λ_{en} = effective lost rate constant for precursor radionuclide n and is given by $\lambda_{en} = L_i + \lambda_{rn}$ where L_i is the total rate constant for all physical transfers of chain member i from the medium (s^{-1})
and K_{in} is defined by

$$K_{11} = \frac{Q_1(0)}{\lambda_{r1}} \tag{5.106}$$

$$K_{in}(n = 1 \rightarrow i-1) = \frac{\sum_{j=n}^{i-1} d_{ji} \lambda_{rj} K_{jn}}{\lambda_{ei} - \lambda_{en}} \tag{5.107}$$

$$K_{ii} = \frac{Q_i(0)}{\lambda_{ri}} - \sum_{n=1}^{i-1} K_{in} \tag{5.108}$$

where d_{ji} is the fraction [branching factor] of precursor radionuclide transitions (chain member j) that result in production of the chain member i.

78

In the models, the solution for radioactive decay is used to determine factors for decay and ingrowth for each member of the chain. The following method is used to determine these factors. First, the first member of the chan is assumed to have an activity of 1 and the fraction of decay of material and the ingrowth into the other chain members is calculated using Equation (5.104) assuming a specific time step. For the plume model, the time step is 900 seconds (15 minutes); for the puff model, the time step is based on the number of puff released per hour (3600 seconds/ number of puff per hour). Next, the second member of the chain is assumed to have an activity of 1 (all the other members have an activity of zero), and the decay and ingrowth factors are calculated for each member of the chain. The same technique is then applied to each member of the chain. Once all the factors have been calculated, the decay results can be constructed into a table like Table 5.10, where f_{11} is the fraction of chain member 1 left after decay (for the specific time period), f_{12} is the fraction of ingrowth to chain member 2 from chain member 1, f_{1n} is the fraction of ingrowth into chain member n from chain member 1, and so on. As ingrowth does not move up the chain, the fraction of ingrowth to chain 1 from chain 2 would be zero. Thus, the bottom triangle of the table (f_{ij} where the row number (i) is larger than the column number(j)), would contain zeros.

For the plume model, the in-transit decay and ingrowth is determined by applying the fractions (f_{ij}) to each of the time steps (time [distance/wind speed] to reach the receptor/900 seconds) required to reach the receptor. In the puff model, the decay is calculated at the end of each time step.

Table 5.10   Chain Member Decay/Ingrowth Fraction Matrix

	Chain Member 1	Chain Member 2	. . .	Chain Member n
Chain Member 1	f_{11}	f_{12}	. . .	f_{1n}
Chain Member 2	f_{21}	f_{22}	. . .	f_{2n}
. . .	. . .	. . .	. . .	. . .
Chain Member n	f_{n1}	f_{n2}	. . .	f_{nn}

5.3.7   Depletion

Mass balance is maintained in the atmospheric codes. Material deposited on the surface by dry and wet deposition is removed from the material in the plume or puff, which acts to reduce the release rate or mass of the puff. Material is not selectively removed from the bottom of the plume or puff. This approach is a variation of the source-depletion model described in Hanna et al. (1982).

In the atmosphere, deposition results in a mass deficit in the layer of air next to the surface. Source-depletion models instantaneously propagate this deficit through the full vertical extent of the plume or puff. This propagation is unrealistic, particularly in stable atmospheric conditions. Using the resistance analogy to estimate the deposition velocities does not deal with this problem explicitly. However, using the resistance analogy results in lower deposition velocities during stable conditions, which reduces the magnitude of the error.

For a puff model, the mass from each puff is determined from analytical integration of the deposition flux over the area covered by the puff and computation interval. The mass removed from each puff to account for dry deposition of particles and wet and dry deposition of gases is computed using

$$\Delta Q_d = \Delta t \int_{\boldsymbol{q}=0}^{2\boldsymbol{p}} \int_{r=0}^{\infty} d_v \, \boldsymbol{c} \, r \, dr \, d\boldsymbol{q} \tag{5.109}$$

where $?Q_d$ is the amount of mass removed and d_v is d_{dd} for particles or $d_{dd} + d_{dw}$ for gases.

Substituting the definition of ? from Equation (5.25) and performing the integration, the decrease in material becomes

$$\Delta Q_d = \frac{2 \, d_v \, Q G(z) \, \Delta t}{\sqrt{2\boldsymbol{p}} \, \boldsymbol{s}_z} \tag{5.110}$$

During periods of precipitation, the additional rate of mass loss from a puff by washout of particles is determined by integrating the washout rate over the area covered by the puff and is calculated as follows

$$\Delta Q_w = \Delta t \int_{\boldsymbol{q}=0}^{2\boldsymbol{p}} \int_{r=0}^{\infty} \frac{\Lambda \, Q \exp(-\dfrac{r^2}{2\boldsymbol{s}_r^2})}{2\boldsymbol{p} \, \boldsymbol{s}_r^2} \, r \, dr \, d\boldsymbol{q} \tag{5.111}$$

When this integration is carried out, the rate of loss is equal to the product of the mass in the puff and the washout coefficient. Thus,

$$\Delta Q_w = Q \, [1 - \exp(-\Lambda \Delta t)] \tag{5.112}$$

This loss of mass is distributed throughout the puff.

In the puff models, depletion is computed at the end of each time step. If there is no precipitation, the mass remaining in the puff is computed assuming only dry deposition as

$$Q_{ij+1} = Q_{ij} - \Delta Q_d \tag{5.113}$$

where i is the puff index and j is the time index. When there is precipitation, the depletion calculation is

$$Q_{ij+1} = Q_{ij} \exp(-\Lambda \Delta t) - \Delta Q_d \tag{5.114}$$

For the plume models, a different approach is taken. The depletion of the source term per unit distance is given by Van der Hoven (1968) as

$$\frac{dQ'}{dx} = -\int_{-\infty}^{\infty} w(x, y) \, dy = -\int_{-\infty}^{\infty} d_v c \, dy \tag{5.115}$$

For a point source, the integral can be solved to give

$$\frac{dQ'}{dx} = -\sqrt{\frac{2}{p}} \frac{d_v Q'}{U s_z} G(z) \tag{5.116}$$

which can be rearranged as

$$\int_{x_1}^{x_2} \frac{dQ'}{Q'} = -\sqrt{\frac{2}{p}} \frac{v_d}{U} \int_{x_1}^{x_2} \frac{G(z)}{s_z} dx \tag{5.117}$$

Solving the integral on the left hand side gives

$$\ln \frac{Q'(x_2)}{Q'(x_1)} = -\sqrt{\frac{2}{p}} \frac{v_d}{U} \int_{x_1}^{x_2} \frac{G(z)}{s_z} dx \tag{5.118}$$

or

$$Q'(x_2) = Q'(x_1) \exp(-\sqrt{\frac{2}{p}} \frac{v_d}{U} \int_{x_1}^{x_2} \frac{G(z)}{s_z} dx) \tag{5.119}$$

The integral of the reflection term, G(z), and the vertical dispersion coefficient normally can not be solved explicitly. In the codes, the integral is approximated numerically using a simple trapezoidal rule. The integral is calculated at each receptor in the order of closest receptor to the source to farthest receptor from the source. Thus, the depletion for a receptor would be the sum of the depletion at the previous receptor and the Equation (5.119), where x_1 is the distance to the previous receptor and x_2 is the distance to the current receptor. If the distance between receptors is greater than twice the distance from the previous receptor to the source, depletion is calculated at an intermediate point that is twice the distance from the previous receptor to the source. For example, if the two receptors are at 100 and 500 meters, the depletion at two intermediate points, 200 and 400 meters, would be calculated. The depletion at 500 meters would be the sum of the depletion at 400 meters and Equation (5.119) with $x_1 = 400$ meters and $x_2 = 500$ meters. These intermediate points are calculated to prevent unreasonable errors in the estimation of the integral. To prevent errors in estimating the integral, depletion does not occur for distances less than 100 meters from the source.

At a downwind distance where $s_z = 1.2\,H$ (e.g., the concentration is uniformly mixed through the boundary layer), Equation (5.115) can be solved to give

$$Q'(x_2) = Q'(x_1) \exp(-\frac{v_d [x_2 - x_1]}{UH})$$
(5.120)

As Equation (5.120) does not involve an integral, at the distances where $s_z = 1.2H$, Equation (5.120) is used to estimate the depletion of the plume. If this distance where $s_z = 1.2H$ occurs between two receptors, the depletion is a sum of the depletion calculated by Equation (5.119) up to the distance where $s_z = 1.2H$ and Equation (5.120) for the rest of the distance to the second receptor.

For the area source, depletion is assume to not occur until the plume is far enough distance downwind that the area source is similar to a point source (5a for the sector average model and 10 a for the non-sector average model). Under this assumption, the equations used for depletion is the same as for a point source (i.e., Equations 5.119 and 5.120). In cases of very large area source, the model tends to underpredict the amount that is depleted. Thus, the concentration and deposition rates would be overpredicted.

For the washout of particles, the integration of deposition term can be solved to give the following

$$Q'(x_2) = Q'(x_1) \exp(-\Lambda\Delta t)$$
(5.121)

where ? t is $(x_2 - x_1)/U$.

5.4 <u>FINITE PLUME SUBMERSION DOSE</u>

Earlier versions of GENII calculated cloud-shine doses using either a semi-infinite cloud model or a finite-plume model based on the model developed for MESORAD (Scherpelz, et al. 1986, page 31). The first of these models assumes that activity is uniformly distributed through a large volume, and the second assumes that activity is concentrated in a finite number of points distributed through a volume to represent the actual activity distribution. The use of the semi-infinite cloud model is usually inappropriate in the immediate vicinity of the release point, and application of the MESORAD finite-plume model to cloud-shine dose estimates near the release point did not prove satisfactory. Consequently, the cloud-shine dose models in GENII V.2 have been significantly revised from those used in earlier versions. The basic framework is that also implemented in the RASCAL 3.0 emergency response code (Sjoreen et al. 2001).

Cloud-shine models based on line sources and plane sources have been developed that are analogous to the point-source model used in MESORAD. These models are used, along with the point-source model, until plumes and puffs grow to sufficient size that the assumptions associated with the semi-infinite cloud model are met. In the MESORAD point-source model, point-source dose rates were calculated as a function of distance for each radionuclide from gamma energies. This calculation, which was repetitive and time consuming, has been deleted. The finite-plume cloud-shine models in GENII make use of precalculated dose rate vs distance curves. These curves are provided in the radionuclide data base for each radionuclide for a 1 Ci (0.01 Sv) point source, and a 1 Ci/m (0.01 Sv/m) infinite line source. The remainder of this section describes the GENII V.2 cloud-shine models.

5.4.1 <u>Puff Model cloud-shine dose calculations</u>

There are three stages in GENII puff-model cloud-shine dose calculations. Near the source where puff dimensions are small compared to the mean path length of photons, GENII uses a revised version of the point-kernel dose model. When the puff radius becomes sufficient (s_y=400 m), cloud-shine dose rates beneath the centerline of the plume are calculated using an infinite slab model. The dose rate at ground-level is calculated assuming that the activity in the plume is equally divided among 10 horizontal slabs with slab heights determined by the release height and vertical dispersion coefficients. The change in dose rate with distance from slabs is due only to buildup and absorption of photons; the change in dose rate across the plume is proportional to the crosswind variation of activity concentration in the slab. This model will be discussed further, shortly. Finally, when the vertical dimensions of the plume become sufficient (s_z=400 m), cloud-shine is calculated using a semi-infinite cloud model.

The point-kernel integration is based on the formulation of the MESORAD finite-puff cloud shine model (Scherpelz et al., 1986; Ramsdell et al., 1988). This model first calculates composite characteristics (photon energies, photons per disintegration, etc.) of the gamma radiation from the radionuclide mix in a puff. Next, the model calculates the dose rate vs distance from a point source having the composite characteristics using

$$D'_p(\rho) = \frac{2.13 \times 10^6}{4\pi\rho^2} \sum_{\gamma} \left[f_\gamma B_\gamma(\mu_\gamma,\rho) e^{-\mu_{a\gamma}\rho} E_\gamma T_\gamma W_\gamma \right] \qquad (5.122)$$

where

$D_p'(?)$ = dose rate in (rem/h)/Ci,
$?$ = distance from point source,
$f_?$ = fraction of disintegrations producing ?s of energy $E_?$,
$B_?(\mu_?,?)$ = buildup factor for air,
$\mu_{a?}$ = linear attenuation factor for air,
$E_?$ = gamma energy,
$T_?$ = mass energy absorption coefficient $(\mu_{t?}/?_t)$, and
$W_?$ = ratio of whole body dose to surface dose.

The constant 2.13 x 10^6 is a collection of units conversion constants to give dose rate in (rem/h)/Ci. The components of the constant are described following Eq. (19) in Scherpelz, et al (1986).

The model then calculates the dose rate at ground level as a function of horizontal distance from the ground-level position of center of the puff. This calculation involves summation over volume elements distributed throughout the puff.

$$D'(r) = \sum_i \sum_j \sum_k D'_p(\rho_{ijk}) M_{ijk} \qquad (5.123)$$

where

$D'(r)$ = dose rate at r,
r = distance from the receptor to the projection of the puff center on the ground,
i,j,k = indices associated with the volume elements,
$D'_p(?_{ijk})$ = dose rate at distance ? from a point source in volume element ijk,
$?_{ijk}$ = distance from the center of the volume element ijk to the receptor, and
M_{ijk} = fraction of the total puff activity in volume element ijk.

The dose at a receptor for a period is accumulated by summing the product of dose rates and the time step for all puffs for all time steps in the period.

In GENII, this process has been modified by eliminating the calculation of composite characteristics from the gamma energies. In its place, the puff models calculate the dose rate vs distance from a point source having all of the activity in the puff. Thus, Eq. (5.123) is replaced by

$$D'_p(\rho) = \sum_{n=1}^{N} Q_n D'_{pn}(\rho) \qquad (5.124)$$

where

N = number of radionuclides,
Q_n = activity of radionuclide n in the puff, and
$D'_{pn}(?)$ = dose rate (Sv/s) at distance ? from a 1-Ci point source of radionuclide n.

In the GENII puff models, the puff is divided into ten layers with each layer containing one tenth of the activity. The number of annular rings has been fixed at six, with each ring containing the one sixth of the puff activity, and the number of sectors has been fixed at 12. The fraction of activity in each volume element becomes 1/720 of the total activity. In GENII, then, Eq. (5.124) becomes

$$D'(r) = \frac{1}{720} \sum_i \sum_j \sum_k D'_p(\rho_{ijk}).$$ (5.124)

The dose factors are interpolated from tabulated data. Symmetry is used to reduce the computational load.

When the horizontal dispersion parameter reaches 400 m, the puff radius is large enough that the horizontal variations in the cloud shine dose rate are directly proportional to the horizontal variation in concentration in the puff. At this point, MESORAD changed to a semi-infinite cloud model. The GENII puff models change from the point-source based cloud-shine model to a new plane-source based model. The plane-source model assumes that the puff is a vertical cylinder as is done in the point source model. However, rather than assuming that activity is distributed among volume elements, the activity is assumed to be concentrated on 10 horizontal slabs (planes).

To calculate the activity in each slab, first integrate the concentration at the center of the puff (y=0) vertically from the bottom of the puff to the top. This is similar to the integration done in calculating the depletion from wet deposition

$$\langle \chi \rangle_n = \int_{-\infty}^{\infty} \frac{Q_n}{(2\pi)^{3/2} \sigma_y^2 \sigma_z} \exp\left[-0.5 \left(\frac{r}{\sigma_y} \right)^2 \right] \exp\left[-0.5 \left(\frac{h_e}{\sigma_z} \right)^2 \right] dz = \frac{Q_n}{2\pi\sigma_y^2} \exp\left[-0.5 \left(\frac{r}{\sigma_y} \right)^2 \right]$$ (5.125)

where $\langle \chi \rangle_n$ is the vertically integrated concentration of radionuclide n at the center of the puff. This concentration is then divided by the number of slabs (10) to get the concentration in each slab.

Within the cylinder, the vertical position of the slabs is determined by the effective release height, the mixing layer thickness, and the vertical dispersion coefficient. When a Gaussian distribution is partitioned so the area under the curve is divided into ten equal parts and the center of mass of each part is determined, these centers of mass fall at $\pm0.127s$, $\pm0.385s$, $\pm0.674s$, $\pm1.037s$, and $\pm1.645s$. Using this as a basis, the slab heights are initially estimated as $h_e\pm0.127s_z$, $h_e\pm0.385s_z$, $h_e\pm0.674s_z$, $h_e\pm1.037s_z$, and $h_e\pm1.645s_z$. The initial heights may lie below ground level or above the top of the mixing layer. Any heights that fall outside these bounds are adjusted to account for reflection by the boundaries. Signs of heights that are negative are changed to positive, and heights (h_p) that are above the mixing layer are replaced by $2H-h_p$.

The dose rate at ground level from a slab is calculated as

$$D'_{sl}(r,z) = \frac{0.1\sum\limits_{n} Q_n DF_{pn}}{2\pi\sigma_y^2} \exp\left[-0.5\left(\frac{r}{\sigma_y}\right)^2\right](1 + k\mu z)\exp(-\mu z) \qquad (5.126)$$

where

z = height of the slab above the receptor, which is assumed to be at 1 m (m),

DF_{pn} = dose factor radionuclide n for an infinite plane [(Sv/s)/(Ci/m^2)],

μ = total gamma-ray absorption coefficient for air (m^{-1}), and

k = ratio of energy in scattered photons to absorbed energy.

The infinite plane dose factor contained in Federal Guidance Report 12 (Eckerman and Ryman, 1993) are used.

In Eq. (5.126), the term $(1+k\mu z)$ represents the buildup factor due to scattered photons, and $\exp(-\mu z)$ represents the absorption of energy by the air. These terms are discussed by Healy and Baker (1968) and Healy (1984). In GENII, μ and k are assumed to be constants with values appropriate for ~0.7 MeV photons ($\mu=0.01$, $k=1.4$) based on Fig. 16.4 of Healy (1984).

Ultimately, the dose rate at a receptor is

$$D'_{sl}(r) = \frac{0.1\sum\limits_{n} Q_n DF_{pn}}{2\pi\sigma_y^2} \exp\left[-0.5\left(\frac{r}{\sigma_y}\right)^2\right]\sum\limits_{i=1}^{10}\left(1 + k\mu z_i\right)\exp(-\mu z_i) \qquad (5.127)$$

where the summation is over all slabs.

When the vertical extent of the puff is sufficient for the semi-infinite cloud model to be appropriate ($s_z > 400$ m, or a uniformly-mixed plume with a vertical depth >600 m), the cloud-shine dose rate is calculated using the semi-infinite cloud model

$$D'(r) = [\chi(r)/Q]\sum\limits_{n} Q_n DF_{sicn} \qquad (5.128)$$

where $[?(r)/Q]$ is calculated using Eq. (5.25) or a variation thereof, as appropriate. The semi-infinite dose factors from Federal Guidance Report 12 (Eckerman and Ryman, 1993) are used in this calculation.

5.4.2 Plume Model cloud-shine dose calculations

A new set of models has been developed for cloud-shine dose calculations in the GENII plume models. These calculations proceed in a manner similar to the calculations for the puff models. Near the source, the plume is divided into a large number of equal-strength line sources spaced to properly represent the distribution of activity in the plume. The dose rates from these line sources are used to calculate the ground-level dose rate as a function of horizontal distance from the plume axis. This relationship is then used to calculate dose rates and 15-min doses at

receptor locations. When the width of the plume is sufficient (s_y = 400 m), the GENII plume models switch from the line source model to an infinite slab model. Finally, when the vertical dimensions of the plume are sufficient to make the semi-infinite cloud model appropriate (s_z = 400 m or uniformly mixed plume with a thickness of 600 m), the GENII models switch to a semi-infinite cloud model.

Dose rates from line sources are calculated using

$$D'_l(\rho) = \sum_{n=1}^{N} Q'_{ln} D'_n(\rho) \tag{5.129}$$

where

$D'_l(?)$ = dose rate (Sv/s) at a distance ? from and infinite line source of Q'_{ln} (Ci/m),

Q'_{ln} = line source strength (Ci/m), Q'_{ln} = Q'_n /u where Q'_n is in Ci/s, and

$D'_n(?)$ = line source dose rate factor [(Sv/s)/(Ci/m)] for radionuclide n.

Equation (5.129) is analogous to Eq. (5.124) with changes in the definitions of source term and dose factors.

The line-source dose rates are combined to get the plume dose rate by summing over all line sources, just as the point-source dose rates were combined to get a puff dose rate. The number of line sources used is determined by the horizontal dispersion parameter, s_y. If s_y is greater than 200 m, 100 lines (10x10) are used to describe the concentration distribution in the plume. Otherwise, the concentration distribution is described by 36 lines (6x6). In either case, the lines are spaced horizontally and vertically such that all lines represent the same fraction of the activity in the plume. The plume dose rate is given by

$$D'(y) \quad \underline{\quad\quad}$$

where

x = downwind distance (m) to a point beneath the plume centerline at the intersection of the plume centerline and a perpendicular line passing through the receptor,

R = distance (m) from the release point to the receptor, and

h_e = effective release height.

In the case of a ground-level release and a receptor on the plume centerline, the correction factor will be one. However, generally the correction factor is less than one. For a 0.7 MeV photon, the correction factor given by Eq. (5.131) corresponds to a receptor at a position approximately 100 m off of the plume centerline. Doses will be slightly over estimated for receptors that are closer than 100 m and slightly under estimated for receptors that are farther than 100 m from the centerline.

When the horizontal dispersion parameter exceeds 400 m, the GENII plume models shift from a line-source based finite plume model to an infinite plane model. The infinite plane model used by the plume models is similar to the model used by the puff models. The differences between the two models are associated with the calculation of concentrations, not with the cloud shine calculation. Thus, Eq. (5.127) for puffs becomes

$$D'_{sl}(r) = \frac{0.1\sum_n Q'_n DF_{pn}}{2\pi\sigma_y u} \exp\left[-0.5\left(\frac{r}{\sigma_y}\right)^2\right] \sum_{i=1}^{10} \left(1 + k\mu z_i\right)\exp\left(-\mu z_i\right) \qquad (5.132)$$

for plumes.

Finally, when the vertical extent of the plume is sufficient ($s_z = 400$ m, or a uniformly mixed plume with a 600 m vertical extent), the plume models shift to a semi-infinite plume cloud shine model. Equation (5.128) for becomes

$$D'(r) = [\chi(r)/Q']\sum_n Q'_n DF_{sicn} \qquad (5.133)$$

where ?(r)/Q' is calculated using Eq. (5.1) or a variation thereof, as appropriate.

5.5 METEOROLOGICAL DATA

The atmospheric model calculations are based on the use of observed meteorological data. Observed meteorological data can occur in two general forms, hourly meteorological data where the data the meteorological information is recorded every hour and a joint frequency distribution of wind speed, wind direction, and atmospheric stability, in which the hourly meteorological data has been summarized. Two programs, HRLYPROC and JJFDPROC, were developed that take meteorological data stored in the hourly (HRLYPROC) or joint frequency distribution (JJFDPROC) and manipulate the data into a single format that can be read by the atmospheric models. The users' manual discusses the input data required by the model, adjustments to the data, and calculation of meteorological variables that are not directly measured, such as stability classifications.

6.0 SURFACE WATER TRANSPORT MODULE

The surface water module is included to represent transport through surface waters to the terrestrial environment. The surface water models included in GENII-V2 are described in this section. They are the same as those implemented in GENII Version 1.485 (Napier et al. 1988) and are the same as those employed in the LADTAP II computer program (Strenge, Peloquin, and Whelan 1986). All surface water transport models are based on work of Whelan as described in a report by Codell, Key, and Whelan (1982).

Surface water transport models are included for estimating the water concentration resulting from acute and chronic release to non-tidal rivers, and chronic releases to near-shore lake environments. Non-tidal rivers are freshwater bodies with unidirectional flow in definable channels. Near-shore lake environments are surface water areas that are near the shores of large open bodies of water and that have a straight shoreline, constant depth, and steady-state, unidirectional flow parallel to the shore.

6.1 RIVER TRANSPORT MODELS

River transport models include representation of acute releases and chronic releases. Acute releases are those resulting from short-term events that release radionuclides over a period of a few hours or days. Chronic releases are continuous and constant releases over periods of weeks to years.

The surface water program solves for radionuclide concentrations in a river or large lake under the following limiting assumptions (Codell, Key, and Whelan 1982):

- · constant flow depth
- · constant downstream or alongshore velocity
- · straight river channel
- · constant lateral dispersion coefficient
- · continuous point discharge release of effluent
- · constant river width.

Codell, Key, and Whelan (1982) note that applications of models similar to those described here should be restricted to those portions of the near-shore zone of a river or lake that are removed from the influence of the discharge. Initial dilution near the point of discharge is usually controlled by the momentum effects of jets.

For non-tidal rivers, the assumed release point is on the near shore of the river with the water usage point (e.g. water treatment plant intake) located at a downstream distance x and a laterally offshore distance y. The water concentration (steady-state) at the downstream location is given by the following equation (NRC 1977; Codell, Key and Whelan 1982):

$$C_{wi} = \frac{Q_b \, C_{oi}}{u \, d \, B} \left\{ 1 + 2 \sum_{n=1}^{\infty} \left[e^{-(\frac{n \, \pmb{p}}{u \, d \, B})^2 E_y \, u \, d^2 x} \right] \cos \left(\frac{n \, \pmb{p} \, y}{B} \right) \right\} \qquad (6.1)$$

where C_{wi} = concentration of radionuclide i in surface water at water usage location w, after continuous release for a given time period (Bq/L)

$\quad$ B = constant river width (m)

$\quad$ C_{oi} = initial concentration radionuclide i in effluent entering the water body (Bq/L)

$\quad$ d = constant flow depth (m)

$\quad$ E_y = constant lateral turbulent dispersion coefficient (m^2/sec)

$\quad$ Q_b = effluent discharge rate to the receiving water body (m^3/sec)

$\quad$ u = average flow velocity (m/sec)

$\quad$ x = longitudinal (downstream) distance to location of interest (m)

$\quad$ y = lateral distance to water intake point from the near shore (m).

The product of Q_b and C_{oi} is provided in the primary data communication file for water flux (WFF), with appropriate unit conversions.

When the water usage location is far downstream and lateral mixing is nearly complete, the water concentration may calculated from the river dilution volume as follows:

$$C_{wi} = \frac{Q_{wi}}{V_w} \qquad (6.2)$$

where Q_{wi} = average release rate of radionuclide i to the surface water body (Bq/sec)

$\quad$ V_w = dilution volume for the receiving water body representative of the usage location (L/sec).

The dilution volume is equivalent to a river flow rate. This representation is available for use with all exposure pathways associated with contaminated water usage; in GENII-V2 this is called the "Flow Dilution Model."

Acute surface water releases are considered by allowing the calculation of a time-integrated average water concentration, E_{wi}, as:

$$E_{wi} = \frac{3.1688\,\text{E-}8}{T_w} \int_0^{T_w} \frac{q_{wi}(t)}{V}\,dt = \frac{3.1688\,\text{E-}8\;Q_{wi}}{T_w\,V} \qquad (6.3)$$

where E_{wi} = time-integrated average water concentration at water usage location i for radionuclide i (Bq/L)

$\quad$ $q_{wi}(t)$= instantaneous release rate of radionuclide i to water as a function of time, t, (Bq/sec)

$\quad$ T_w = period over which the release to water occurs for water usage location w (yr),

$\quad$ 3.1688E-8 = unit conversion factor (yr/sec),

and other terms are as previously defined. The instantaneous release rate is given in the primary data communication file for release to the surface water (WFF) as a function of time. The data for the time points is integrated and averaged over the release period to estimate a value for the average release rate, Q_{wi}.

6.2 NEAR-SHORE LAKE TRANSPORT MODELS

Near-shore lake environments are described by a model similar to the river model. The NRC (1977) has suggested use of a quasi-steady-state model valid for simulating contaminant transport in near-shore lake environments for distances up to 16 miles (27 km). The model is represented by the following equation:

$$C_{wi} = \left(\frac{C_{oi}\,Q_b}{p \times \sqrt{E_y\,E_z}} \right) e^{-\frac{y^2\,u}{4\,x\,E_y}} \sum_{i=-\infty}^{+\infty} e^{-\frac{(2\,i\,d\,-\,z)^2\,u}{4\,x\,E_z}} \qquad (6.4)$$

where E_z = vertical turbulent dispersion coefficient (m^2/sec)

$\quad$ z = depth of discharge (m),

$\quad$ C_{oi} = initial concentration radionuclide i in effluent entering the water body (Bq/L)

$\quad$ d = constant long-shore flow depth (m)

$\quad$ E_y = constant lateral turbulent dispersion coefficient (m^2/sec)

$\quad$ u = average flow velocity (m/sec)

$\quad$ x = longitudinal (long-shore) distance to location of interest (m)

$$y = \text{lateral (off-shore) distance to water intake point from the near shore (m).}$$

and other terms are as previously defined.

Equations (6.1) and (6.4) require values for the lateral and vertical dispersion coefficients. Dispersion coefficients should be obtained by site-specific tracer studies whenever possible. Accurately defining dispersion coefficients for all river or lake environments under all conditions is difficult, if not impossible at this time. However, rough estimates can be defined. The coefficients are defined such that representative properties of the water body are considered when making estimates.

In the absence of site-specific estimates of dispersion coefficients Strenge, Peloquin, and Whelan (1986) have suggested use of the following expressions:

$$E_y = 0.06\,d\ u \qquad\qquad\qquad (6.5)$$

and

$$E_z = 0.0059\,d\ u \qquad\qquad\qquad (6.6)$$

Even though Equations (6.5) and (6.6) were developed for rivers, they are also suggested for use with near-shore lake environments.

6.3 DECAY IN TRANSIT

All radionuclides are allowed to undergo chain decay and ingrowth of progeny during the time of transit from the release point to the exposure point as follows.

$$C_{ri}(T_{yr}) = C_{rwi}(T_{yr})\,\exp^{-\lambda_i Tt_r} \qquad\qquad\qquad (6.7)$$

where $C_{ri}(T_{yr})$ = average annual water concentration for radionuclide i at recreational water usage location r (Bq/L)

$C_{rwi}(T_{yr})$ = average annual water concentration for radionuclide i evaluated at the recreational usage location r, but uncorrected for decay in transit from the release point (Bq/L)

Tt_r = travel time from water release point to recreational water usage location r (y)

T_{yr} = one year averaging period (y)

λ_i = radiological decay constant for radionuclide i (y^{-1})

Decay is handled using the decay processor described in Appendix C.

7.0 NEAR-FIELD EXPOSURE MODULE

The near-field exposure module evaluates exposure scenarios in which the exposed individual is near the initial contamination. The module evaluates transfer of activity from the contaminated media (soil) to the individual. The processes dominated by local phenomena, rather than long-range transport, are included in this component. Not included are exposure pathways that involve either waterborne or airborne transport (discussed in Sections 8 and 9). Most of the applications for the near-field component deal with spills, initial contamination, buried wastes, or intruders. These exposure scenarios may all be considered to represent chronic exposure situations (although the original process of contamination may itself be acute).

The soil model and the exposure models in the near-field component are described in this section. The soil model is described first, followed by the exposure models arranged by exposure route (external, ingestion, and inhalation). Exposure pathways included in the near-field component are listed in Table 7.1 with an indication of the mechanism by which the exposure medium becomes contaminated. Many of the models in this component are the same as those described for the chronic exposure module (Section 9).

The output from the near-field component is the medium concentration represented as an average value over the exposure duration, generally annual averages.

Table 7.1 Exposure Pathways for the Near-field Analysis

Exposure Medium	Exposure Mechanism	Exposure Route
Soil	soil ingestion	ingestion
	ground exposure	external
Air	resuspension	inhalation
	resuspension	external
Food crops	crop soil contamination	ingestion
Animal products	animal feed contamination	ingestion

7.1 COMMUNICATION INTERFACES

The input files for the Near-field Exposure Module are the global input data file (GID), one soil concentration file (a PDCF), and one auxiliary data communication files (radionuclide master date library). The soil concentration file (SCF) is generated by a source term module. Output from the Near-Field Exposure Module is written to the Exposure Pathway File (EPF).

7.2 SOIL MODEL

The near-field module soil model allows calculation of surface soil concentrations as a function of time with consideration of: 1) release from buried waste, 2) biotic transport from deep soil to surface soil, 3) leaching from deep soil and surface soil, 4) loss from deep and surface soil from plant harvest, and 5) redistribution of activity from deep soil to surface soil by human intrusion. The soil model is applied separately for each exposure pathway allowing different soil concentrations to be used to evaluate each exposure pathway. For example, different soil concentrations can be defined for leafy vegetable crops consumed directly by humans, and for forage crops used by milk animals.

The general soil model is illustrated in Figure 7.1. This figure shows the three compartments considered in the model: surface zone, subsurface zone, and contaminated subsurface zone (waste source). The surface soil is the portion from which resuspension occurs. Radionuclides may be lost from the surface soil through harvest removal, radiological decay, and leaching out of the surface soil layer. In situations where subsurface contamination exists, radionuclides may be contained in waste packages or simply distributed in the soil. If the waste is in a package, it may be released to the soil using the waste package decomposition model (represented as a single user-defined loss rate constant).

99

Radionuclides in the available subsurface soil (those not in packages) may be transported to the surface soils by root uptake by plants, by physical transport by native animals, or by human interactions through intrusion into the waste that results in redistribution of waste from deep to surface soil. Note that the model does not include transfer from the surface zone to either of the other two zones. All losses from the surface zone (harvest removal or leaching) are assumed to leave the system.

The soil model allows evaluation of the soil concentration (surface soil and subsurface soil) at the start of the intake period, accounting for prior transfer from the waste package. When the source includes a waste package, the time of placement represents the start of the calculation, with the time to the start of the intake period being greater than or equal to zero. Also, the time of loss of institutional control (prior to the start of intake) is given. The soil model then evaluates the soil and waste package concentration at the start of the intake period. After the start of intake, the soil model is used to follow the change in soil compartment concentrations as intake is evaluated. The models and sub-models defined in the following section are applied on an annual basis as indicated by the time period parameter, T_{yr}, representing a one-year time period.

Application of the soil model for agricultural pathways involves defining the fraction of roots that are in each of the soil zones. Although the model explicitly considers three compartments, the fourth is conceptually an uncontaminated layer in between the surface and deep soils. Although neglected in the model, the existence of such a layer may be simulated by appropriate application of the rooting depth fractions (see Section 7.3.1). A fraction of plant roots may be described as located in the surface soil layer, and another fraction as located in the deep soil. These two fractions may add to less than one if a clean soil layer intervenes.

The model is defined by differential equations that describe the change of concentration in each compartment as a function of time. The three compartments are ordered according to transfers from one to the next. The first compartment in the model is the subsurface waste package compartment because it has no input from other compartments. The second is the subsurface soil zone because it has input from only the subsurface waste package compartment. The third is the surface soil zone because it has input from the other two compartments. This numbering is used in the nomenclature of the equations to follow.

The total amount of a radionuclide in the subsurface waste package zone is decreased by radioactive decay and by loss to the subsurface soil zone. Material may also be redistributed to the surface soil zone; however, this redistribution is represented as a step function applied at the start of the analysis (representing a human action). The redistribution results in an increased initial amount of the radionuclide in the surface soil zone. The differential equations for the three soil model compartments are defined in terms of the amount of each radionuclide chain member present in units of atoms. This representation is used for ease of understanding and ease of solving the equations. The final solutions are evaluated using the radioactive decay-chain processor described in Appendix C. The general solutions presented in that appendix are given in terms of atom units and activity units. The differential equation for the subsurface contaminated zone (waste package) is as follows:

$$\frac{d\ A_{1i}(t)}{dt} = -(R_{pi} + \lambda_i)\ A_{1i}(t) \tag{7.1}$$

where $A_{1i}(t)$ = amount of radionuclide i in the subsurface waste package zone at time, t (atoms)

R_{pi} = release rate constant for release of radionuclide i from the waste package (y^{-1})

λ_i = radioactive decay rate constant for radionuclide i (y^{-1}).

The amount of a radionuclide in the subsurface soil zone is increased by the transfer of activity from the subsurface waste package zone, and by loss from radioactive decay and from transfer by biotic processes (plant and animal) to the surface soil zone. The differential equation for the subsurface soil zone is as follows:

$$\frac{d\ A_{2i}(t)}{dt} = R_{pi}\ A_{1i}(t) - (R_{bi} + R_{ai} + \lambda_i)\ A_{2i}(t) \tag{7.2}$$

where $A_{2i}(t)$ = amount of radionuclide i in the subsurface soil zone at time, t (atoms)

R_{bi} = rate constant for transfer of radionuclide i from the subsurface soil zone to the surface soil zone by biotic plant transport (y^{-1})

R_{ai} = rate constant for transfer of radionuclide i from the subsurface soil zone to the surface soil zone by biotic animal transport (y^{-1})

and other terms are as previously defined.

The amount of radionuclide in the surface soil zone is increased by biotic transfer from the subsurface soil zone, and is decreased by losses from radioactive decay, leaching, and harvest. The decrease from harvest is modeled as a step function following the time of harvest and does not appear in the differential equation for the surface zone. The differential equation for the surface soil zone is as follows:

$$\frac{d\ A_{3i}(t)}{dt} = (R_{bi} + R_{ai})\ A_{2i}(t) - (\lambda_{Li} + \lambda_i)\ A_{3i} \tag{7.3}$$

where $A_{3i}(t)$ = amount of radionuclide i in the surface soil zone at time, t (atoms)

λ_{Li} = rate constant for leaching of radionuclide from the surface soil zone (y^{-1})

and other terms are as previously defined.

Application of the soil model requires that the initial amount of each radionuclide in each compartment be known. The agricultural exposure pathway models are generally expressed per

unit area or unit weight (e.g. kg) basis. To use the general radioactive decay-chain algorithm with the soil model, it is necessary to express the amount of each radionuclide on the same basis. If all compartments occupied the same area, then the calculation could be performed on the basis of unit area. Because the waste package compartment is not likely to be the same size as an agricultural field, this option is not generally possible. For cases in which there is no waste package compartment, the unit area basis is the obvious choice. The equations in the following description of the soil models are expressed per unit area of soil. When a waste package compartment is present, it is necessary to express the equations per total activity (by defining the total area and depth of each compartment).

Various aspects of the soil model are described in the following subsections. The first section describes the method to reconcile definition of total activity versus activity per unit area or mass. The remaining sections describe estimation methods for the transfer rate constants defined for the soil model.

7.2.1 Method for Reconciliation of Activity Units

When the soil model is applied without the waste package compartment, the calculations can easily be performed on the basis of unit area of contaminated soil. This approach requires a minimum of parameter definitions. When the deep soil or waste package compartment is included, consideration must be given to the total amount of activity in each compartment. This requires definition of additional parameters to relate contaminated area to total contamination in the surface and subsurface compartments. In all cases involving the subsurface compartment, it is assumed that the surface and subsurface compartments occupy the same area. The correlation of units requires definition of the total activity per unit area in the waste package and the area of contamination for the surface and subsurface soil layers. These parameters are used in the following manner to implement the general decay algorithm solution. The total activity per unit area in the package and subsurface soil zones are calculated as follows:

$$Q_{1si}(t) = C_{1si}(t) \; r_d \; d_d \tag{7.4}$$

and

$$Q_{2si}(t) = C_{2si}(t) \; r_w \; d_d \tag{7.5}$$

where $Q_{1si}(t)$ = total areal activity of radionuclide i in waste package at soil usage location s at a time t (Bq)

$Q_{2si}(t)$ = total areal activity of radionuclide i in subsurface soil at soil usage location s at a time t (Bq)

$C_{1si}(t)$ = waste package concentration at soil location s for radionuclide i at time t (Bq/m^2)

$C_{2si}(t) =$ subsurface soil concentration at soil location s for radionuclide i at time t (Bq/m^2)

$\rho_d =$ density of subsurface soil (kg/m^3)

$\rho_w =$ density of waste package (kg/m^3)

$d_d =$ thickness of deep soil/waste package layer (m).

The total activity in the waste package compartment for radionuclide i and soil usage location s is expressed by the parameter, $Q_{1si}(t)$. When the waste package compartment is included, the soil model is evaluated using the general solution algorithm with activity expressed as the total amount per unit area in each compartment $(Q_{1si}, Q_{2si},$ and $Q_{3si})$. The result of the evaluation for the surface compartment is then converted back to units of activity per unit area or mass for use in the terrestrial pathway equations.

7.2.2 Release Rate from Subsurface Waste Package

The rate of release of activity from the subsurface waste package is provided by the user. A rate constant is required for release directly to the subsurface soil layer (R_{wpi}).

7.2.3 Biotic Transfer to the Surface by Plants

Plants whose roots penetrate contaminated soil layers may transport activity to the surface (McKenzie et al. 1985). This activity becomes part of the surface soil over a period of time. The rate of transfer to the surface is estimated as follows:

$$R_{pi} = \sum_{l=1}^{N_p} \frac{B_{vli} \; RP_{dl} \; B_l}{d_d \; r_d} \tag{7.6}$$

where $R_{pi} =$ rate constant for transfer of radionuclide i from the subsurface soil zone to the surface soil zone by plant transport (y^{-1})

$N_p =$ number of plant species considered to contribute to plant transport. In GENII-V2, a single composite plant type is used for computational convenience.

$B_{vli} =$ soil-to-plant concentration ratio for plant species l and radionuclide i (Bq/g dry plant per Bq/g dry soil)

$RP_{dl} =$ fraction of plant l roots in the subsurface (deep) soil zone (dimensionless).

$B_l =$ total biomass production of plant l for a year $(kg/m^2/y)$

d_d = thickness of subsurface soil layer (m)

ρ_d = subsurface soil density (kg/m^3).

7.2.4 Biotic Transfer to the Surface by Animals

Activity may be transported from the subsurface soil layer to the surface soil by insects and mammals. The rate of transfer is estimated as follows:

$$R_{ai} = \sum_{j=1}^{N_a} \frac{M_j}{d_d\, r_d} \tag{7.7}$$

where R_{ai} = rate constant for transfer of radionuclide i from the subsurface soil zone to the surface soil zone by animal transport (y^{-1})

N_a =   number of animal species considered in evaluation of animal transport to the surface soil layer (dimensionless). In GENI-V2, a single composite animal is used

M_j = transfer rate factor for movement of soil from the subsurface layer to the surface layer by animal j (kg/m^2/y).   The composite rates used in GENII-V2 are given in Table 7.2

and other terms are as previously defined. The burrowing activity is assumed to result in excavation of soil, all of which is deposited on the surface soil layer. Excavation rates and fractions from each soil stratum for three sets of environmental conditions are given in Table 7.2.

Table 7.2 Biotic Transport Fractions and Rates (adapted from McKenzie et al. 1986)

| | Transport Fractions | | |
| | Environmental Condition | | |
Depth to Deep Soil	Arid	Humid	Agricultural
< 0.15 m	1.0	1.0	1.0
0.15 - 0.5 m	0.81	0.90	0.90
0.5 - 1.0 m	0.19	0.096	0.096
1.0 - 1.5 m	0.02	0.006	0.006
1.5 - 2.0 m	0.008	0.0005	0.0005
> 2.0 m	0.002	0.0005	0.0005
Excavation Rate (m^3/m^{2}y)	9.41E-4	7.48E-4	7.48E-4

7.2.5 Leaching from the Surface Soil Zone

Removal from the surface soils through leaching into deeper soils is treated by means of a soil removal rate constant. For surface soils the rate constant, λ_{si}, is a correction for long-term leaching of deposited radionuclides out of the surface soil (rooting and resuspension zones. The values for λ_{si} are calculated using the formula of Baes and Sharp (1981):

$$\lambda_{si} = \frac{10^{-2} \ (P + I - E)}{d_s \ \theta_s \left[1 + \frac{10^3 \ 10^{-6} \ \rho_s}{\theta_s} \ Kd_{si} \right]} \tag{7.8}$$

where λ_{si} = removal rate constant for activity of radionuclide i in the surface soil layer (y^{-1})

P = total annual precipitation (cm/y)

I = total irrigation rate (cm/y)

E = total evapotranspiration rate (cm/y)

ρ_s = surface soil bulk density (kg/m^3)

θ_s = surface soil volumetric water content (mL/cm^3)

Kd_{si} = surface soil distribution coefficient for radionuclide i (mL/g)

10^{-2} = units conversion factor (m/cm)

10^3 = units conversion factor (g/kg)

10^{-6} = units conversion factor (m^3/ml)

7.2.6 Loss by Harvest

Loss of activity from the surface soil zone is modeled as a step function applied at the end of each calculational year. The amount of loss is calculated from the plant concentration at harvest, the annual plant yield, and the root penetration factors and the soil concentrations at harvest. The calculation is represented by the following equation.

$$C_{3si}(t_+) = C_{3si}(t_-) \left[\left(C_{3si} - C_{ci}(Th_c) \ Y_c \ \frac{C_{3si}(t_-) \ RP_{sc}}{C_{3si}(t_-) \ RP_{sc} + C_{2si}(t_-) \ RP_{dc}} \right) / C_{3si} \right] \tag{7.9}$$

where $C_{3si}(t_+)$=surface soil concentration at soil location s for radionuclide i after correction for harvest removal at time t (Bq/m^2)

$C_{3si}(t_-) =$ surface soil concentration at soil location s for radionuclide i before correction for harvest removal at time t (Bq/m^2)

$C_{ci}(Th_c) =$ crop c concentration for radionuclide i at time of harvest (Bq/kg)

$C_{2si}(t_-) =$ subsurface soil concentration at soil location s for radionuclide i before correction for harvest removal at time t (Bq/m^2)

$Y_c =$ annual yield of crop c (kg/m^2)

$RP_{sc} =$ fraction of crop c roots in the surface soil zone (dimensionless)

$RP_{dc} =$ fraction of crop c roots in the subsurface (deep) soil zone (dimensionless).

The multiplicative term represents the average fraction of the contaminant in soil to that in crops over the year; this term is used rather than a simple subtraction of amount harvested because, for short-lived radionuclides, the amount harvested over the year may actually be larger than the amount remaining in the soil at the end of the year.

7.2.7 Transfer by Redistribution

Activity in the subsurface waste package may be manually redistributed to the surface soil zone by application of a redistribution factor at the start of the analysis. The redistribution is intended to represent human disruption of a site. The manual redistribution factor relates the resultant surface soil concentration, in Bq/kg, to the initial subsurface concentration, in Bq/kg. Because the surface soil is modeled as a slab 15 cm thick, a scenario in which deep soils are brought up and overlay the previous surface would use a manual redistribution factor of 1.0. If the resulting surface contamination was a mix of 75% clean soil and 25% contaminated soil, the manual redistribution factor would be 0.25. Scenarios that result in proportionately more or less redistribution would be simple multiples.

7.2.8 Soil Model Application to Near-Field Exposure Module

The near-field component is designed to evaluate scenarios beginning with initial contamination of the soil. In this model the initial contamination may be in the surface soil layer, deep soil (subsurface) layer, or subsurface waste source package. The initial conditions for the near-field soil model involve definition of the activity of each radionuclide in the three zones. The initial activity is defined using a source definition module that allows the user to define the soil or waste package concentration and the volume (length, width, and depth) of each of the soil model compartments. The soil model provides estimates of soil concentration as a function of time for evaluation of media concentrations for each exposure pathway. The estimation of exposure pathway media concentrations is described in the following sections.

7.3 EXTERNAL EXPOSURE PATHWAYS

External exposure pathways associated with the near-field component include immersion in air contaminated by resuspension, and standing on the contaminated ground. The ground external dose pathway includes modification of dose rate to account for a small area of contamination.

7.3.1 External Air Immersion

This pathway is similar to the chronic pathway for immersion in a contaminated plume (Sections 5.4 or 9.3.1). The air concentration is related directly to the soil concentration by resuspension of soil particles. The air concentration used to evaluate the immersion dose is assumed to be proportional to the time-integral of soil concentration. The time-integral of the surface soil concentration for a one-year period is evaluated using Equation (7.3). The equation specific to the near-field analysis can be written as follows.

$$C_{esi}(T_{yr}) = \left[C_{3si}(T_{yr}) + \frac{R_{bit}}{\lambda_i T_{yr}} \left(T_{yr} - \frac{1 - e^{-\lambda_i T_{yr}}}{\lambda_I} \right) \right] \tag{7.10}$$

where $C_{esi}(T_{yr})$ = time-average of surface soil concentration for radionuclide i (Bq/m^2)

$C_{3si}(T_{yr})$ = average surface soil concentration during the current year from material present in the surface soil zone at the start of the year (Bq/m^2)

R_{bit} = biotic transport rate from deep soil to surface soil (Bq/m$^2 \cdot$y^{-1})

T_{yr} = one year period of exposure (y).

The average surface soil concentration is evaluated using the initial concentration with decay and loss processes followed during the year.

The biotic transport rate is evaluated from the biotic transport rate constants and the average activity in the subsurface soil zone over the current year, as follows.

$$R_{bit} = \frac{R_{bi} + R_{ai}}{T_{yr}} \int_0^{T_{yr}} C_{2si}(t)\, dt \tag{7.11}$$

where $C_{2si}(T_{yr})$ = subsurface soil concentration for radionuclide i as a function of time (Bq/m^2)

R_{bi} = rate constant for transfer of activity from subsurface soil to surface soil for plant species (y^{-1})

R_{ai} = rate constant for transfer of activity from subsurface soil to surface soil for animal species (y^{-1})

and other terms are as previously defined. The biotic transport rate constants are defined in Section 7.2.3 (for plants) and in Section 7.2.4 (for animals). The chain decay processor (Appendix C) is used to perform the analyses.

The average surface soil concentration is used to estimate the average air concentration for external exposure as follows

$$C_{eai}(T_{yr}) = RF_a \, C_{esi}(T_{yr}) \qquad\qquad (7.12)$$

where $C_{eai}(T_{yr})$ =   average air concentration from resuspension for radionuclide i (Bq/m^3)

$\quad\quad$ RF_a =   resuspension factor for soil exposure (m^{-1})

and other terms are as previously defined. The resuspension factor may be estimated using either a time-dependent function developed by Anspaugh et al. (1975) or by means of a mass loading factor. Both of these methods are defined in Section 9.5.2.

7.3.2 External Ground Exposure

An individual standing on the contaminated source may be exposed to external radiation. The exposure estimate is based on the time-integral of surface soil concentration over the exposure period (one year). The soil concentration equation is the same as that for the soil suspension and air immersion pathway, Equation (7.10), divided by normalizing factors of surface soil depth and density, d_s (m) and $?_s$ (kg/m^3), to give units of Bq/kg. Because of the large variability that may exist in the exposure conditions at any given site, a correction factor that modifies the default area exposure pathway assumptions for contaminated areas of less than infinite size is provided.

For external exposures from contaminated soils, Kennedy et al. (1982) conducted a sensitivity study for various beta-gamma emitters to determine the exposure rate versus source area. The results of the calculations are shown in Figure 7.2. Since the curves of Figure 7.2 are parallel, Kennedy et al. (1982) determined that the correction factor for small sites was independent of radiation energy. They approximated the correction factor as a suite of four line-segments, as shown in Figure 7.3. This correction factor is applied to sites of surface area less than 1250 square meters.

7.4 INGESTION EXPOSURE PATHWAYS

The near-field component includes ingestion pathways related to use of the surface soil. Pathways include food crop ingestion, animal product ingestion, and inadvertent soil ingestion.
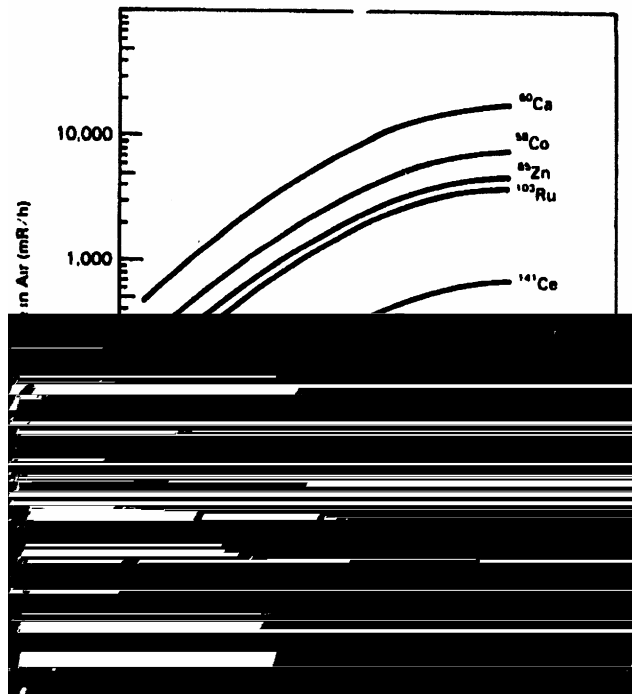

Figure 7.2. Exposure rate versus source area for selected gamma emitters (Kennedy et al. 1982)
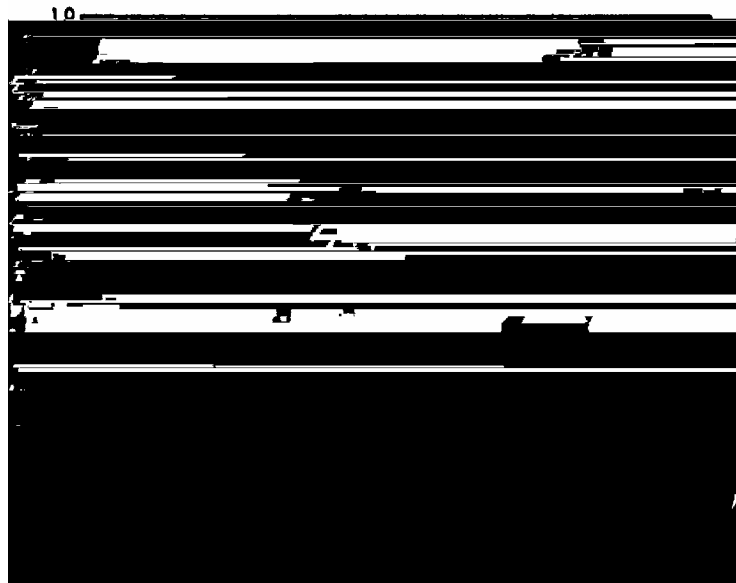

Figure 7.3. Infinite plane external dose rate correction factor for small sites (Kennedy et al. 1982)

7.4.1 Food Crop Ingestion

Crops grown in the contaminated surface soil may become contaminated from root uptake and resuspension of activity. The average plant concentration over a one-year period from resuspension and deposition is based on the average soil concentration during the year. The average soil concentration includes components from initial contamination in the surface soil zone, plus material transferred from the subsurface zone by biotic transport. The average surface soil concentration is given as follows.

$$C_{3ci}(T_{yr}) = C_{3si}(T_{yr}) + \frac{R_{bit}}{\lambda_i\, T_{yr}} \left[T_{yr} - \frac{1 - e^{-\lambda_i T_{yr}}}{\lambda_i} \right] \tag{7.13}$$

where $C_{3ci}(T_{yr})$ =   average concentration of radionuclide i in farmland soil for crop type c during the current year (Bq/m^2),

$C_{3si}(T_{yr})$ =   is the average concentration during the current year of radionuclide i in surface soil at location s (where crop c is grown) from contamination present at the start of the year (Bq/m^2)

R_{bit} =   biotic transport rate from deep soil to surface soil (Bq/m$^2\cdot$y^{-1})

T_{yr} =   one year period of exposure (y).

The biotic transport rate from subsurface soil to surface soil is evaluated using Equation (7.11).

The concentration in the crop at harvest from resuspension deposition is then calculated as follows.

$$C_{dci}(T_{yr}) = \frac{3.15E\,7\; C_{3ci}(t)\; RF_c\; Vd_i\; r_{ac}\; Tv_c}{B_c} \left[\frac{1 - e^{-\lambda_{ei} Tg_c 2.74E\text{-}3}}{\lambda_{ei}} \right] \tag{7.14}$$

where $C_{dci}(T_{yr})$ =concentration of radionuclide i on plant type c at harvest from deposition processes for a one year period (Bq/kg wet weight)

T_{yr} =   one year exposure period (y)

r_{ac} =   interception fraction from airborne dry deposition for plant type c (dimensionless)

$C_{3ci}(T_{yr})$ =   average surface soil concentration during the current year for crop c (Bq/m^2)

RF_c =   resuspension factor for crop soil (m^{-1})

Vd_i = deposition velocity of radionuclide i (m/s)

Tv_c = translocation factor for plant type c (dimensionless)

B_c = total standing biomass for plant type c (kg wet weight/m^2)

λ_{ei} = effective loss rate constant from plant surfaces representing weathering and radioactive decay for radionuclide i (y^{-1})

$$\lambda_{ei} = \lambda_{wi} + \lambda_i$$

λ_{wi} = weathering rate constant for crops for radionuclide i (y^{-1})

Tg_c = crop growing period for plant type c (d)

3.15E7 = units conversion factor (sec/y)

2.74E-3 = units conversion factor (y/d).

The plant concentration from root uptake is evaluated using Equation (7.15),

$$C_{rci}(T_{yr}) = \left[\frac{C_{3ci}(T_{yr})\ Bv_{ci}\ f_c\ RP_{sc}}{P_3} + \frac{C_{2si}(T_{yr})\ Bv_{ci}\ f_c\ RP_{dc}}{P_2} \right] \tag{7.15}$$

where $C_{rci}(T_{yr})$ = concentration of radionuclide i in crop type c from root uptake pathways for a one year period (Bq/kg wet weight)

Bv_{ci} = concentration ratio for root uptake of radionuclide i in crop type c (Bq/kg dry plant per Bq/kg dry soil)

f_c = dry-to-wet ratio for plant type c (kg dry plant/kg wet plant)

RP_{dc} = fraction of plant type c roots in subsurface (deep) soil zone (dimensionless)

P_3 = areal soil density of farmland soil (kg/m^2)

$C_{2si}(T_{yr})$ = average concentration of radionuclide i in subsurface soil zone during the current year (Bq/m^2)

RP_{sc} = fraction of plant type c roots in surface soil zone (dimensionless)

P_2 = areal soil density of subsurface soil zone (kg/m^2)

The total plant concentration at harvest is the sum of the contributions from resuspension and root uptake, as follows.

where $C_{hci}(T_{yr})$ is the average concentration in plant type c at harvest for a one year period (Bq/kg wet weight) and other terms are as previously defined.

The concentration in crops at the time of consumption by humans is evaluated by accounting for decay between harvest and consumption, according to Equation (7.18), as follows.

where $C_{csi}(T_{yr})=$ concentration of radionuclide i in crop type c at location s at the time of consumption over a one year period (Bq/kg wet weight)

Th_c =   holdup delay time between harvest and consumption for crop type c (d)

λ_i =   radiological decay constant for radionuclide i (y^{-1}).

The average concentration at consumption of a one-year intake period is the output from the near-field exposure component.

7.4.2 Animal Product Ingestion

T_{yr} = one year exposure period (y)

Fa_i = transfer coefficient that relates daily intake rate by an animal to the concentration in an edible animal product a (Bq/L milk per Bq/d for milk and Bq/kg meat per Bq/d for meat)

$C_{3ai}(T_{yr})$ = average concentration of radionuclide i in soil consumed by animals for a year t (Bq/kg dry soil)

$C_{cfi}(T_{yr})$ = concentration of radionuclide i in animal feed type f at time of consumption for a one year period (Bq/kg wet weight)

d_{as} = fraction of animal type a soil intake that is contaminated (dimensionless)

U_{as} = daily soil intake rate for animal type a (kg/d)

N_{af} = number of feed types, f, fed to animal type a

d_{af} = fraction of animal type a feed type f intake that is contaminated (dimensionless)

U_{af} = daily feed intake rate for animal type a of feed type f (kg/d)

and other terms are as previously defined.

The concentration in animal products at the time of consumption is evaluated by accounting for decay between harvest and consumption. The holdup delay time defines this time period. The calculation is performed using the decay processor (see Appendix C). The calculation is represented for the parent radionuclide as follows.

$$C_{asi}(T_{yr}) = C_{hai}(T_{yr}) \, e^{-\lambda_i \, Th_a \, 2.74E\text{-}3} \tag{7.19}$$

where $C_{asi}(T_{yr})$ = concentration of radionuclide i in animal product a at usage location s at the time of consumption for a one year period (Bq/kg wet weight)

Th_a = holdup delay time between harvest and consumption for animal product a (d)

λ_i = radiological decay constant for radionuclide i (y^{-1}).

7.4.3 Inadvertent Soil Ingestion

An individual coming in contact with soil in the contaminated surface layer may be exposed via inadvertent ingestion of soil. The exposure estimate is based on the average surface soil concentration over the exposure period (one year). The equation is as follows.

$$C_{dsi}(T_{yr}) = \frac{10^3}{10^4 \, \rho_s \, d_s} \left[C_{3si}(T_{yr}) + \frac{R_{bit}}{\lambda_i T_{yr}} \left(T_{yr} - \frac{1 - e^{-\lambda_i T_{yr}}}{\lambda_i} \right) \right] \qquad (7.20)$$

where $C_{dsi}(T_{yr})$ =   average concentration in surface soil for radionuclide i in soil consumed during the current year (Bq/kg)

$C_{3si}(T_{yr})$ =   average surface soil concentration for radionuclide i during the current year (Bq/m^2)

ρ_s =   density of surface soil (g/cm^3)

d_s =   thickness of surface soil layer (cm)

R_{bit} =   biotic transport rate from deep soil to surface soil (Bq/m$^2\cdot$y^{-1})

10^4 =   units conversion factor (cm^2/m^2)

10^3 =   units conversion factor (g/kg)

The biotic transport rate is the same as defined by Equation (7.11) for the resuspension pathways.

7.5 INHALATION EXPOSURE PATHWAYS

One inhalation exposure pathway is included in the near-field component: inhalation of particulate material in suspended soil.

7.5.1 Soil Suspension Air Inhalation

Inhalation of suspended activity is based on the average air concentration above the contaminated surface soil during the exposure period. This air concentration is defined by Equation (7.12) for the air immersion exposure pathway.

7.6 SPECIAL MODELS FOR TRITIUM AND CARBON-14

In the GENII Version 2 system, tritium and carbon-14 are assumed to be in a specific activity equilibrium with contaminated air or water. There is no defined root uptake pathway directly from soil. Therefore, in the Near Field module, all pathways related to root uptake (plant and animal concentrations) are set equal to zero. Refer to Section 9.6 for details on the models for chronic uptake by these radionuclides.

8.0 ACUTE EXPOSURE MODULE

The acute exposure module provides estimates of exposure media concentration for short-term contamination of air or surface water. The models are defined to represent situations in which the release or exposure occurs over a relatively short period of time. Acute releases are typically on the order of a few hours or less, with exposures occurring over a period from a few hours (e.g., for air transport) to a few months (e.g., deposition onto soil with subsequent external or crop ingestion exposure). Exposure from residual contamination in soil could also occur over a many-year period and is included in the analysis. The module includes models to represent the amount of activity in soil as a function of time and exposure pathway models for specific exposure routes (external, ingestion, and inhalation).

The acute exposure module estimates exposure media concentrations for the exposure pathways listed in Table 8.1. As indicated in the table, some exposure pathways are not evaluated for the acute exposure period, but only for exposure to residual contamination during the long-term period immediately following the acute period. Model details are given in the following sections.

Table 8.1 Exposure Pathways for the Acute Exposure Module

Transport Mode	Exposure Pathways	Exposure Period
atmospheric	air inhalation	acute/chronic
	soil resuspension	chronic
	soil ingestion	chronic
	air external	acute/chronic
	ground exposure	chronic
	food crops	chronic
	animal products	chronic
surface water	drinking water ingestion	acute/chronic
	shower volatilization	acute/chronic
	shower water ingestion	acute/chronic
	irrigated food crops	chronic
	irrigation/animal products	chronic
	ground exposure	chronic
	swimming ingestion	acute/chronic
	swimming external	acute/chronic
	swimming water ingestion	acute/chronic
	boating external	acute/chronic
	shoreline sediment ingestion	chronic
	shoreline external	chronic
	aquatic foods	chronic
soil contamination	soil resuspension	chronic
	soil ingestion	chronic
	ground exposure	chronic

8.1 COMMUNICATION INTERFACES

　　The input files for the acute exposure module are the global input data file (GID), the atmospheric concentration file (ACF), the water concentration file (WCF), and one auxiliary data communication file (the radionuclide master data library). The communication interfaces are indicated in Figure 8.1. The atmospheric concentration file is generated by the atmospheric transport module. The water concentration file (WCF) is generated by the surface water module (or other external program that is capable of generating the water concentration file information). The GID file section for the acute exposure module is generated by the user interface program. It contains information describing the scope of the analysis and all user-provided input parameters for an analysis. The structure and content of the files are given in Appendix A and B.

　　The output from the acute terrestrial and aquatic pathway module is the concentration in various media to which individuals or populations are exposed. Along with each concentration, the duration of exposure is also provided, representing the period of integration for the particular pathway. This information is provided in a primary data communication file, the exposure pathway media concentration output file (EPF).

8.2 SOIL MODEL

The soil model used with the acute exposure model is represented by the surface soil compartment of the general soil model. This model allows calculation of surface soil concentrations as a function of time with consideration of: 1) leaching from surface soil, 2) deposition from air to surface soil, 3) irrigation deposition from water to surface soil, and 4) loss from surface soil from plant harvest. The soil model is applied separately for each exposure pathway allowing different soil concentrations to be used to evaluate each exposure pathway. For example, different soil concentrations can be defined for leafy vegetable crops consumed directly by humans, and for forage crops used by milk animals.

The portion of the soil model used in the acute calculations is illustrated in Figure 8.2. This figure shows that the only compartment considered in the model is the surface zone. The surface soil is the portion on which deposition from the atmosphere and irrigation occurs, and that from which resuspension occurs. For acute scenarios, it is the only portion of the soil model that is used. Radionuclides may be lost from the surface soil through harvest removal, radiological decay, and leaching out of the surface soil layer. All losses from the surface zone (harvest removal or leaching) are assumed to leave the system.

The soil model allows evaluation of the soil concentration at the start of the intake period, accounting for initial atmospheric deposition and irrigation water deposition. After the start of intake, the soil model is used to follow the change in soil compartment concentrations as intake is evaluated. The models and sub-models defined in the following section are applied on an annual basis as indicated by the time period parameter, T_{yr}, representing a one-year time period.

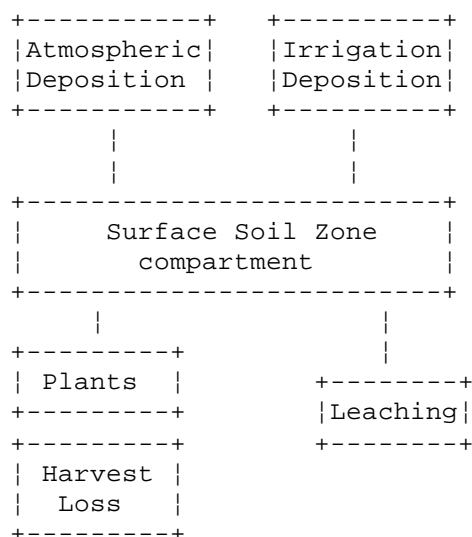

Figure 8.2 Acute Module Soil Model

118

The model is defined by a differential equation that describes the change of concentration as a function of time. The decrease from harvest is modeled as a step function following the time of harvest and does not appear in the differential equation for the surface zone. The differential equation for acute releases for the surface soil zone is as follows:

$$\frac{d\,A_i(t)}{dt} = -\left(\lambda_{Li} + \lambda_i\right)A_{0i} \qquad (8.1)$$

where $A_{oi}=$ initial deposition on soil surface at time 0, (atoms)

$A_i(t)$ = amount of radionuclide i in the surface soil zone at time t (atoms)

λ_{Li} = rate constant for leaching of radionuclide from the surface soil zone (y^{-1}).

Various aspects of the soil model are described in the following subsections. The first section describes definition of the initial amount in the surface compartment for air and water deposition for acute releases. The remaining sections describe estimation methods for the transfer rate constants defined for the soil model.

8.2.1 Activity from Air and Water Deposition

The soil model for acute releases requires an estimate of the initial activity in each compartment. The initial activity in the surface soil is related to the transport analysis for air or water.

The initial soil activity can be evaluated using estimates from the atmospheric transport component deposition estimates. The deposition estimate parameter for acute releases is the amount of a radionuclide deposited at a location from wet or dry deposition (two parameter values). The deposition amounts may be summed to give the total deposition, taken to be the initial amount present at time zero (assuming a short acute release and deposition period).

For deposition from surface water, the initial soil activity is given as follows.

$$C_{si}(0) = E_{wi}\,IR_w\,T_w \qquad (8.2)$$

where $C_{si}(0)=$ initial concentration of radionuclide i in soil at soil usage location s (Bq/m^2)

$E_{wi} =$ time integrated average water concentration at surface water usage location w for radionuclide i over the time of contamination passage (Equation 6.3) (Bq/L)

$IR_w =$ application rate of irrigation water at water usage location w $(L/m^2/sec)$

$T_w =$ period over which the release of contamination to surface water passes the usage location w (sec).

In application of the water deposition equation, the water usage location w is defined as the source for irrigation water for soil usage location s. Groundwater is not considered for acute waterborne transport because of the long delay times involved in transport through aquifers. Acute releases to groundwater are considered to result in chronic sources for use of groundwater.

8.2.2 Leaching from the Surface Soil Zone

Removal from the surface soils through leaching into deeper soils is treated by means of a soil removal rate constant. For surface soils the rate constant, λ_{si}, is a correction for long-term leaching of deposited radionuclides out of the surface soil (rooting and resuspension zones). The values for λ_{si} are calculated using the formula of Baes and Sharp (1981):

$$\lambda_{si} = \frac{10^{-2} \ (P + I - E)}{d_s \ \theta_s \left[1 + \dfrac{10^3 \ 10^{-6} \ \rho_s}{\theta_s} \ Kd_{si} \right]} \tag{8.3}$$

where λ_{si} =   removal rate constant for activity of radionuclide i in the surface soil layer (y^{-1})

$\quad\quad\quad$ P =   total annual precipitation (cm/y)

$\quad\quad\quad$ I =   total irrigation rate (cm/y)

$\quad\quad\quad$ E =   total evapotranspiration rate (cm/y)

$\quad\quad\quad$ ρ_s =   surface soil bulk density (kg/m^3)

$\quad\quad\quad$ θ_s =   surface soil volumetric water content (mL/cm^3)

$\quad\quad Kd_{si}$ =   surface soil distribution coefficient for radionuclide i (mL/g)

$\quad\quad 10^{-2}$ =   units conversion factor (m/cm)

$\quad\quad\ 10^3$ =   units conversion factor (g/kg)

$\quad\quad 10^{-6}$ =   units conversion factor (m^3/ml)

8.2.3 Loss by Harvest

Loss of activity from the surface soil zone is modeled as a step function applied at the end of each calculational year. The amount of loss is calculated from the plant concentration at harvest, the annual plant yield, and the root penetration factors and the soil concentrations at harvest. The calculation is represented by the following equation.

$$C_{si}(t_+) = C_{si}(t_-)[(C_{si} - C_{ci}(Th_c) \ Y_c)/C_{si}]$$ (8.4)

where $C_{si}(t_+)$ = surface soil concentration at soil location s for radionuclide i after correction for harvest removal at time t (Bq/m^2)

$C_{si}(t_-)$ = surface soil concentration at soil location s for radionuclide i before correction for harvest removal at time t (Bq/m^2)

$C_{ci}(Th_c)$ = crop c concentration for radionuclide i at time of harvest (Bq/kg)

Y_c = annual yield of crop c (kg/m^2)

The multiplicative term represents the average fraction of the contaminant in soil to that in crops over the year; this term is used rather than a simple subtraction of amount harvested because, for short-lived radionuclides, the amount harvested over the year may actually be larger than the amount remaining in the soil at the end of the year.

8.3 EXTERNAL EXPOSURE PATHWAYS

Four exposure pathways are included for acute releases that involve external exposure from radionuclides in a contaminated medium: immersion in air, standing on ground, swimming or boating in water, and standing on shoreline.

8.3.1 External Plume Immersion

Two models are available for estimation of the dose from exposure to external radiation from an airborne plume of radioactivity. The simpler model is based on the assumption that the plume is essentially infinite in size, bounded by the ground plane. This model is referred to as the semi-infinite plume model. The second model is referred to as the finite plume model because it considers the finite dimensions of the plume in evaluation of the dose at the ground-level receptor location.

The output from the semi-infinite plume model is the time-integrated air concentration at the exposure location(s) (Equations 5.20 or 5.27). The output from the finite plume model is the time-integrated radiation dose at the exposure location(s). For both models, the output file (EPF) also contains the exposure period over which the average air concentration or radiation dose apply. Also, for both models, the time-integrated radiation dose or average air concentration are provided in the atmospheric transport output file (ATO) and the only modifications to the values made in the exposure component (other than to select the values for the appropriate exposure location) are to average the time integral, as

$$C_{eai}(T_{ex}) = E_{eai} / T_{ex.}$$ (8.5)

Evaluation of dose or risk for the finite plume model is difficult because of the necessity to consider the finite dimensions of the plume. The structure of the software was designed to include the finite plume dose calculation in the atmospheric transport calculation. This structure was selected because information on the plume dimensions is not available in the exposure module. The acute atmospheric transport module performs a finite-plume dose calculation, and then generates the time-integrated radiation dose at a location in the environment. This approach requires more analysis for the atmospheric transport module (Section 5.4) but less analysis for the acute exposure analysis component.

8.3.2 External Groundshine Model

Radioactivity deposited onto ground can cause exposure to individuals near the contamination. The exposure starts at the time of acute deposition and continues as long as the individual is present and the radioactivity remains in the surface soil zone. The deposition may be from either atmospheric or irrigation deposition. The output of the external exposure analysis from acute deposition is the time-integral of soil concentration over the period of exposure. This concentration is evaluated considering decay and progeny ingrowth according to the soil model (see Section 8.2).

Airborne deposition is assumed to cover the entire region of the defined population group (e.g., sector segment boundary), and all individuals are potentially exposed. The deposition amount is used to evaluate population and individual exposures. For waterborne deposition, the soil contamination is assumed to expose only the maximum individual because water transport pathways (e.g., irrigation) will not result in widespread contamination. The general term used for estimation of radiation dose from soil contamination is as follows:

$$C_{esi}(T_{eg}) = \int_{0}^{T_{eg}} C_{si}(t) \ dt \ / \ (T_{eg} \ d_s \ r_s) \qquad (8.6)$$

where $C_{esi}(T_{eg})$ = time-averaged soil concentration from deposition of activity to soil for radionuclide i (Bq/kg)

d_s = thickness of soil (m)

ρ_s = density of soil (kg/m^3)

T_{eg} = exposure time to contaminated ground (y)

$C_{si}(t)$ = concentration of radionuclide i in soil at soil usage location s as a function of time (Bq/m^2).

This equation is applied to airborne and waterborne deposition defined according to the initial deposition. The soil concentration time integral is evaluated using the radioactive chain-decay processor (see Appendix C).

8.2.3 External Exposure from Aquatic Recreational Activities

Aquatic recreational activities involving external exposure include swimming, external exposure while boating, and external exposure while on shoreline. The output parameter for these exposure pathways is the average water or shoreline sediment concentration over the period of contamination. For swimming and boating, the period of contamination is the acute release water contamination period. For the sediment pathways, the period of contamination is the first year after the initial deposition to sediment.

For swimming and boating pathways, the average water concentration is evaluated from the time-integral average of water concentration E_{wi} given by Equation (6.3), described in Section 6.1. The water concentration is used for swimming and boating activities. For boating, the parameter is represented as $C_{bri}(T_{eb})$, where T_{eb} is the same as T_{ew} (i.e., the exposure time for boating and swimming are the same). The exposure time periods are directly related to the time period of water contamination that is inherent in the evaluation of E_{wi}.

The exposure from recreational activities on shoreline involves estimation of the radionuclide concentration in shoreline sediments. The initial deposition to sediment is estimated from a model developed by Soldat, Robinson, and Baker (1974) relating water concentration to sediment concentration following a long period of deposition. For acute release situations the sediment concentration is estimated directly from the time-integrated water concentration. The initial sediment concentration is estimated as follows.

$$C_{sri}(0) = TC \ E_{wi} \ T_{ew} \qquad (8.7)$$

where $C_{sri}(0)$ = initial concentration of radionuclide i in sediment after the acute water contamination period at location r (Bq/m^2)

E_{wi} = time integral average of water concentration during passage of contaminated water at location r (Bq/L)

T_{ew} = acute release time period of contamination of the water at the location of swimming and boating (y)

TC = transfer constant from water to sediment $(L/m^2/y)$.

The value of the transfer constant was derived for several radionuclides by using data obtained from analyzing water and sediment samples taken from the Columbia River between Richland, Washington, and the river mouth, and from Tillamook Bay, Oregon, 75 km south of the river mouth (Nelson 1965; Toombs and Cutler 1968). This data was analyzed by Soldat, Robinson, and Baker (1974) to derive a value of 2.54×10^4 in units of $L/m^2/y$. Equation (8.7) estimates an effective surface contamination for calculating gamma exposure rates to persons standing on sediment.

The average shoreline sediment concentration over the first year following deposition is the output parameter for the shoreline external dose pathway, and is evaluated as follows:

$$C_{sri}(T_{yr}) = \frac{1}{T_{yr}\, d_{sed}\, \boldsymbol{r}_{sed}} \int_0^{T_{yr}} C_{sri}(t)\ dt \qquad (8.8)$$

where $C_{sri}(T_{yr})$ = average shoreline sediment concentration for radionuclide i for the first year exposure period at recreational water usage location r (Bq/kg)

d_{sed} = thickness of shoreline sediments (m)

ρ_{sed} = density of shoreline sediments (kg/m^3)

T_{yr} = one year exposure duration for shoreline activities at the shoreline recreational usage location (y)

and other terms are as previously defined. The time integration is performed using the radioactive chain-decay processor described in Appendix C.

8.4 ACUTE INGESTION EXPOSURE PATHWAYS

Ingestion exposure pathways included are: 1) terrestrial foods contaminated from soil, airborne deposition, or waterborne deposition, 2) aquatic foods contaminated in surface water, 3) drinking water, and 4) inadvertent soil intake.

8.4.1 Terrestrial Food Pathways

The terrestrial food exposure pathways involve contamination of crops and animal products through direct deposition from air onto soil and crops or from use of contaminated irrigation water for crop production or animal drinking water. The terrestrial food pathways include edible crops of leafy vegetables, other vegetables, fruit, cereal grains, and animal products of cow's milk, beef/meat, poultry, and eggs. Under accidental release conditions, the amount of activity ingested through these pathways is difficult to assess. The annual average parameter values and equilibrium bioaccumulation factors used in the chronic pathway analysis models are not directly applicable in describing radionuclide behavior during the short time periods considered in accidental release situations, but they are useful for estimating the time-integrated dose. The formulation for acute releases takes advantage of this. The formulation is similar to, but an extension of, that used in the Belgian model DOSDIM (Govaerts, Martens, and Kretzchmer 1983). The formulation is also conceptually similar to that used in the model PATHWAY (Whicker and Kirchner 1987), but the current model uses fewer input parameters. The terrestrial food model is the same as the GENII model (Napier et al. 1988) for acute exposure occurring in the autumn season (worst case). This selection was based on results from many applications of GENII Version 1.485 in which the autumn season doses were found to consistently be the highest.

The primary output from this module for the agricultural pathways is the average plant concentration at the time of consumption. The averaging period is the exposure time defined for each agricultural product pathway.

Autumn accidents are assumed to occur immediately before harvest, resulting in no soil uptake for crops for that year, but the maximum concentration from deposition directly onto plants. The initiating parameter in the following equations is the initial deposition onto the plant surfaces. The initial concentration on the edible plant crop from atmospheric deposition (which is the concentration at the time of harvest) can be expressed as:

$$C_{cai}(0) = \frac{r_{ac}\ C_{si}(0)\ Tv_c}{Y_c} \tag{8.9}$$

where $C_{cai}(0)$ = concentration on the plant at the time of harvest for crop c from airborne deposition (Bq/kg wet weight)

r_{ac} = interception fraction for plants of crop type c from airborne deposition (dimensionless)

$C_{si}(0)$ = total deposition for the acute release for deposition at soil usage location s for radionuclide i (Bq/m^2)

Tv_c = translocation factor from plant surfaces to edible parts of the plant (dimensionless)

Y_c = yield of crop type c (Kg wet weight/m^2).

For waterborne deposition, the initial concentration on the edible plant crop at the time of harvest can be expressed as:

$$C_{cwi}(0) = \frac{r_{wc}\ C_{si}(0)\ Tv_c}{Y_c} \tag{8.10}$$

where $C_{cwi}(0)$ = concentration on the plant at the time of harvest for crop c from waterborne deposition (Bq/kg wet weight)

r_{wc} = interception fraction for plants of crop type c from waterborne deposition (dimensionless)

After harvest, a delay period usually occurs before consumption of the food product begins. During this delay, additional radiological decay may occur. For some crops, the consumption period may last for weeks or months. To estimate the average crop concentration, the consumption is assumed to occur at a uniform rate. The average crop concentration is evaluated as follows:

$$C_{csi}(T_{fc}) = \frac{1}{T_{fc}} \int_0^{T_{fc}} \left[C_{cai}(Th_c + t) + C_{cwi}(Th_c + t) \right] dt \qquad (8.11)$$

where $C_{csi}(T_{fc})$ = average crop concentration at usage location s for radionuclide i and crop c over the crop intake period, T_{fc} (Bq/kg wet weight)

T_{fc} = the length of the uptake period for food crop c (d)

Th_c = delay period between harvest and the start of consumption of crop c (d)

Consumption of contaminated animal products is treated in a manner similar to the food crop analysis. The animal is assumed to eat contaminated crops or drink contaminated water and produce contaminated products continuously over the consumption period defined for humans. The beef and milk animal are assumed to be fed fresh forage and stored feed, and to drink contaminated water (for waterborne transport analyses). The concentration in fresh forage and stored feed at the time of harvest is evaluated using Equations (8.9) and/or (8.10), with parameters defined for the forage plant or stored feed plant. The crops are assumed to be harvested immediately following the acute deposition and to be fed to the animals over the following period of consumption by animals. The period of consumption by animals is set equal to the period of animal product consumption by humans. The animal product is assumed to be harvested and consumed by humans continuously during this period. During this period the radionuclide concentration is reduced by radioactive decay. The fraction of each type of feed is included in the calculation with the fraction of forage intake, FR, defined and the stored feed intake fraction calculated as 1 - FR. The intake by animals from fresh forage consumption over the 1-year period is evaluated as follows:

$$I_{fai}(T_{ap}) = \frac{FR \, Q_{fa}}{T_{ap}} \int_0^{T_{ap}} \left[C_{faai}(t) + C_{fwai}(t) \right] dt \qquad (8.12)$$

where $I_{fai}(T_{af})$ = average daily intake of radionuclide i by animal type a from forage crop ingestion over the animal product consumption period, T_{af} (Bq/d)

FR = fraction of animal feed (wet weight basis) that is from fresh forage (dimensionless)

Q_{fa} = daily intake rate of feed by animals of type a (kg wet weight/d)

T_{ap} = animal feed consumption period (equal to human consumption period) for animal product a (d)

$C_{faai}(t)$ = concentration of radionuclide i in fresh forage plant f for animal type a as a function of time for airborne deposition (Bq/Kg wet weight)

$C_{fwai}(t) =$ concentration of radionuclide i in fresh forage plant f for animal type a as a function of time for waterborne deposition (Bq/Kg wet weight).

The parameter $C_{faai}(t)$ is evaluated at time zero using Equation (8.9), and the parameter $C_{fwai}(t)$ is evaluated at time zero using Equation (8.10).

The intake by animals from stored feed consumption over the consumption period of animal product is evaluated as follows:

$$I_{sai}(T_{ap}) = \frac{(1 - FR) Q_{fa}}{T_{ap}} \int_0^{T_{ap}} \left[C_{saai}(t) + C_{swai}(t) \right] dt \qquad (8.13)$$

where $I_{sai}(T_{ap}) =$ average daily intake of radionuclide i by animal type a from stored feed crop ingestion over the animal product consumption period, T_a (Bq/d)

$Q_{fa} =$ daily intake rate of feed by animals of type a (kg wet weight/d)

$C_{saai}(t) =$ concentration of radionuclide i in stored feed plant s for animal type a as a function of time from airborne deposition (Bq/Kg wet weight).

$C_{swai}(t) =$ concentration of radionuclide i in stored feed plant s for animal type a as a function of time from waterborne deposition (Bq/Kg wet weight).

and other terms are as previously defined.

The contribution from animal drinking water is based on the time average of the water concentration for the usage location w, $C_{wwi}(T_{ew})$, evaluated using Equation (6.7).

The average animal product concentration over the human consumption period is evaluated as the sums of the contributions from animal feed (fresh forage and stored feed) and animal drinking water, with correction for decay between production and consumption by humans:

$$C_{asi}(T_{ap}) = \left[(I_{fai}(T_{ap}) + I_{sai}(T_{ap})) + C_{wwi}(T_{ew}) Q_{wa} \right] F_{ai} e^{-I_i Th_a} \qquad (8.14)$$

where $C_{asi}(T_{ap}) =$ average animal product concentration at usage location s for radionuclide i and animal product type a over the animal product intake period, T_a (Bq/kg wet weight)

$F_{ai} =$ transfer coefficient that relates daily intake rate by an animal to the concentration in an edible animal product (Bq/L milk per Bq/d for milk and Bq/Kg meat per Bq/d for meat)

$Q_{wa} =$ water ingestion rate by animal a (L/d)

T_{ap} = the length of the uptake period for animal product a (y)

Th_a = delay period between harvest and the start of consumption of animal product a (d)

and other terms are as previously defined.

The analysis for poultry products (poultry meat and eggs) is evaluated assuming the poultry consume grain and water. The calculation of average animal product concentration for poultry is similar to the calculations defined above for beef and milk. The average daily intake from ingestion of grain is evaluated as:

$$I_{gai}(T_{ap}) = \frac{Q_{fa}}{T_{ap}} \int_0^{T_{ap}} \left[C_{gaai}(t) + C_{gwai}(t) \right] dt \qquad (8.15)$$

where $I_{gai}(T_{ap})$ = average daily intake of radionuclide i by animal type a from grain crop ingestion over the animal product consumption period, T_{ap} (Bq/d)

Q_{fa} = daily intake rate of feed by animals of type a (kg wet weight/d)

$C_{gaai}(t)$ = concentration of radionuclide i in grain for animal type a as a function of time for airborne deposition (Bq/Kg wet weight)

$C_{gwai}(t)$ = concentration of radionuclide i in grain for animal type a as a function of time for waterborne deposition (Bq/Kg wet weight).

and other terms are as previously defined. The contribution from animal drinking water is based on the time integral of the water concentration for the usage location s, C_{wwi}, evaluated by Equation (6.7). The average animal product concentration over the human consumption period is evaluated as follows:

$$C_{asi}(T_{ap}) = \left[I_{gai}(T_{ap}) + C_{wwi}(T_{ew}) Q_{wa} \right] F_{ai} e^{-\lambda_i Th_a} \qquad (8.16)$$

where $C_{asi}(T_{ap})$ = average animal product concentration (for poultry) at usage location s for radionuclide i and animal product type a over the intake period, T_a (Bq/kg wet weight)

F_{ai} = transfer coefficient that relates daily intake rate by an animal to the concentration in an edible animal product (Bq/Kg per Bq/d for poultry meat and eggs)

and other terms are as previously defined.

8.4.2 Aquatic Food Ingestion

Ingestion of contaminated aquatic foods is an exposure pathway considered for the surface water transport pathways. Aquatic foods include fish, crustaceans, mollusks, and aquatic plants. Fish represent organisms exposed in free-flowing rivers, lakes, or sea coasts. Mollusks and invertebrates represent organisms that live in water and feed in sediments. The radionuclide concentration in these organisms is related to the contaminant water concentration through bioaccumulation factors. The time integral of concentration in the organisms (to which individuals are exposed) is calculated from the time-integrated average water concentration, as follows:

$$C_{fwi}(T_{af}) = \frac{E_{wwi}(T_{ew})\ B_{if}\ T_{ew}}{T_{af}}\ e^{-I_i\ Th_f} \tag{8.17}$$

where $C_{fwi}(T_{af})$ =   average concentration of radionuclide i in aquatic food type f at the time of consumption by humans at water usage location w (Bq/kg)

    T_{af} = exposure period for ingestion of aquatic food f (y)

  $E_{wwi}(T_{ew})$ = time-integrated average concentration over the acute release period to water for radionuclide i in water at water usage location w (Equation 6.3) (Bq/L)

    T_{ew} =   acute release time period of contamination of the water (y)

    B_{if} = bioaccumulation factor for radionuclide i and aquatic food type f (Bq/kg wet food per Bq/L water)

    Th_f = time period between harvesting and consumption by humans for aquatic food type f (d).

The time-integrated water concentration is evaluated using Equation (6.3).

A small amount of water may be inadvertently ingested while swimming. For swimming, the average water concentration is evaluated from the time-integral average of water concentration E_{wi} given by Equation (6.3), described in Section 6.1.

8.4.3 Drinking Water Ingestion

Consumption of contaminated drinking water is evaluated from the time integral of water concentration, $E_{wwi}(T_{ew})$ for the acute release. The exposure parameter for this pathway is the time integral of water concentration at the point of intake of domestic water. The water concentration in the surface water body is modified to account for water treatment (optional) and a decay correction for transport through the water distribution system. The time integral of drinking water concentration is divided by the period of contamination to estimate the average water concentration at the point of consumption, as follows:

$$C_{dwi}(T_{dw}) = \frac{E_{wwi}(T_{ew})\, T_{ew}\, TF_i}{T_{dw}}\, e^{-\lambda_i\, Th_d} \tag{8.18}$$

where $C_{dwi}(T_{dw})$ = average drinking water concentration of radionuclide i over the acute water release period for water usage location w (Bq/L)

$\quad$ T_{dw} = period of exposure to the contaminated drinking water (y)

$\quad$ TF_i = water treatment purification factor giving the fraction of radionuclide i remaining in the water after treatment (dimensionless)

$\quad$ Th_d = holdup time between removal of water from the surface water body and consumption by humans (d).

The water concentration time integral at the usage location is evaluated using Equation (6.3).

$\quad$ This concentration is also used in the estimation of ingestion intake from inadvertent ingestion during showering.

8.4.4 Inadvertent Soil Ingestion

$\quad$ Contamination of soil may occur from atmospheric deposition to soil and waterborne deposition to soil from surface water used for irrigation. The initial concentration in the soil is evaluated using the soil model described for deposition from air or water. The output from the exposure analysis for the soil ingestion pathway is the time integrated soil concentration (per unit mass) evaluated as follows:

$$C_{dsi}(T_{si}) = \frac{1}{T_{si}\, \rho_s\, d_{ds}} \int_0^{T_{si}} C_{si}(t)\; dt \tag{8.19}$$

where $C_{dsi}(T_{si})$ = average soil concentration of radionuclide i in soil at soil usage location s over the soil exposure period (Bq/kg)

$\quad$ $C_{si}(t)$ = concentration of radionuclide i in soil as a function of time following initial deposition at soil usage location s (Bq/m^2)

$\quad$ T_{si} = exposure period for direct soil ingestion at soil usage location s (y)

$\quad$ ρ_s = surface soil bulk density (kg/m^3)

$\quad$ d_{ds} = thickness of surface soil layer for the soil ingestion pathway (m).

The initial soil concentration, $C_{si}(0)$, includes contributions from air and surface water deposition as appropriate to the exposure scenario being evaluated. The time-integral of the soil concentration is evaluated using the radioactive decay-chain processor (see Appendix C).

8.5 ACUTE INHALATION EXPOSURE PATHWAYS

Individuals exposed to contaminated air or soil will be subject to inhalation intake of radionuclides. The following two sections provide models for estimation of the exposure parameter for inhalation pathways.

8.5.1 Inhalation of Airborne Contamination

Contamination transported from the release point to the location of individuals may result in inhalation intake. The exposure parameter for this pathway is the average air concentration, which is evaluated as follows.

where $C_{aai}(T_{ai}) =$ average concentration of radionuclide i, at the location of exposure, a (Bq/m^3)

$\quad\quad T_{ai} =$ inhalation exposure period (y)

$\quad\quad Q_{ai} =$ total activity of radionuclide i released during the acute release period (Bq)

$\quad\quad E_a =$ normalized time-integrated air concentration at usage location a $(Bq\ sec/m^3)$, Equation 5.20 or 5.27

$\quad 3.169E-8 =$ units conversion factor (y/sec).

The inhalation exposure period corresponds to the period of passage for the contaminated plume.

8.5.2 Inhalation of Resuspended Activity

$$C_{sai}(T_{rs}) = \frac{M}{T_{rs}} \int_0^{T_{rs}} C_{si}(t) \ dt \qquad (8.21)$$

where $C_{sai}(T_{rs})$ =   average air concentration over the resuspension inhalation exposure time, T_{rs}, from resuspension for radionuclide i at usage location s (Bq y/m^3)

M =   resuspension factor (m^{-1})

T_{rs} =   duration of exposure to resuspended contamination at usage location s (y)

$C_{si}(t)$ =   concentration of radionuclide i in soil as a function of time following initial deposition at soil usage location s (Bq/m^2)

The initial soil concentration, $C_{si}(0)$, includes contributions from air and surface water deposition as appropriate to the exposure scenario being evaluated. The time-integral of the soil concentration is evaluated using the radioactive decay-chain processor (see Appendix C). See Section 9.5.2 for a discussion of the resuspension factor.

8.5.3   Inhalation of Indoor Contaminants from Water

Radionuclides in domestic water may be released during household activities that involve heating and use of water. This pathway is discussed for chronic exposures in Section 9.5.3. In practice, this pathway only applies to radon. The airborne concentration from acute releases is evaluated from the time-integrated water concentration and a volatilization factor, as follows.

$$C_{wvi}(T_{ia}) = \frac{E_{wwi}(T_{ew})\, T_{ew}\, T_{fi}\, K_r}{T_{ia}} e^{-\lambda_i\, Th_w\, 2.74E\text{-}3} \qquad (8.22)$$

where $C_{wvi}(T_{ia})$=   average concentration of radionuclide i in indoor air from volatilization from domestic water over the exposure period (Bq/m^3)

$E_{wwi}(T_{ew})$ =   time-integral average of water concentration at water usage location w over the period of water contamination (Bq/L)

T_{ia} =   exposure time to air contaminated from waterborne radionuclides (y)

TF_i =   water treatment purification factor giving the fraction of radionuclide i remaining in the water after treatment (dimensionless)

λ_i =   radiological decay constant for radionuclide i (y^{-1})

K_r =   Andelman volatilization factor for radionuclide pollutants (L/m^3)

2.74E-3 = units conversion factor (y/d).

The time period for exposure to airborne contaminants, T_{ia}, should not be less that the period of water contamination, T_{ew}. If a shorter exposure period is to be considered, then the water contamination period should be used in the denominator of the above equation in place of the exposure period.

Indoor air is assumed to contain contaminants that have infiltrated from outdoors. The value calculated for $C_{vwi}(T_{yr})$ is then added to the outdoor air concentration calculated using Equations 5.20 or 5.27 to give the total indoor air concentration.

8.6 SPECIAL RADIONUCLIDE MODELS: TRITIUM AND CARBON-14

The models for atmospheric contamination of food and animal feed for ^{3}H and ^{14}C in Section 9.6 apply only to chronic release situations. Acute or accidental releases of these radionuclides will not result in the same levels of contamination of vegetation and animal products. These models have been modified for use with acute releases, as described in this section. The models for ^{3}H are described first, followed by the models for ^{14}C.

A correction is included in both models to account for the contaminated plume being present for only a fraction of the growing period. The time period of plume passage is assumed to be no more than a few hours. This selection is based on the following considerations. Two of the atmospheric dispersion models will run on joint frequency data; each 0.01% (the smallest unit of joint frequency data) is equivalent to about 1 hour of observation time. Using the 95th percentile calculations for any one direction corresponds to no more than about 24 hours/year. A single "instantaneous puff" release corresponds to an exposure of about 0.25 hours duration, which is accumulated on an hourly basis (Section 5.1.7). Therefore, the present acute ^{3}H and ^{14}C models are based on a fractional specific-activity model with an exposure time equal to the time of plume passage. Plant growth rates throughout the growing season are assumed to be linear. This allows an "equilibrium factor" to be applied as the ratio of exposure time divided by growing period.

Studies on the dynamics of tritium uptake and desorption from vegetation have been performed and documented (Fellows, Cataldo, Ligotke, and Napier 1990). For leafy vegetation, this work has shown that tritium enters the free water in the plant and reaches an atom ratio equilibrium, air moisture to plant moisture, very quickly. For alfalfa and grape leaves, this occurred in times of four to eight hours. This is rapid enough that an assumption of complete equilibrium being reached during the course of the accident is not overly conservative. The work by Fellows et al. also showed that tritium is quickly released from the plant back to the atmosphere following removal of the contaminating air. Very little of the tritium is incorporated into the organic portions of the plant. Depending on whether it is day or night, the desorption half-time for tritium varies between two and eight hours. A conservative decorporation half-time of 8 hours is used.

The concentration in air during the period of plume passage is evaluated from the time-integrated average air concentration as follows.

$$C_{caH} = E_c \qquad (8.24)$$

where C_{caH} = average tritium concentration in air during the period of plume passage at the location of crop type c (Bq/m^3)

E_c = time-integrated average air concentration at crop growing location c (Equations 5.20 or 5.27), which incorporates T_e, (Bq/m^3)

During the period of plume passage the plant is assumed to attain equilibrium with tritium in environmental water. The basic models describing uptake and incorporation as organically-bound tritium (OBT) are described in Section 9.6.

For both plants and the animals that eat them, the tritium is assumed to decorporate according to the 8 hour retention half-time. The infinite integral of concentration is equal to $1/\lambda$ = 8 h / ln 2 times the peak tritium concentration.

Releases of elemental tritium gas (HT) are a special case. Hydrogen in the elemental form is not readily taken up into vegetation. However, HT is slowly oxidized into tritiated water (HTO) by microbes in soil. For experiments at Chalk River that ran to equilibrium, Peterson and Davis (2002) found an empirical relationship of 8Bq L^{-1} /(Bq m^3) for the ratio of HTO in air moisture to HT in air. This is used here as a simple approximation for the time integrated result (personal communication, S.-R. Peterson). This allows a simple addition to the model described above, in which all terms remain the same if C_{caH} is approximated as 8 C_{caHT} H.

Uptake of ^{14}C into plants is assumed via photosynthesis. It is assumed that any new growth fixes ^{14}C and ^{12}C at ratios the same as in the air during the passage of the plume. However, only a small portion of the total biomass of the plant would be fixed during the acute plume passage period. Therefore, an approximation to the attained concentration is obtained by using the specific-activity approach times the fraction of the growing period represented by plume passage. This technique is the same as others described in this report, because the other approaches all use the time-integrated air concentration, independent of time. Likewise, the ^{14}C model does not require a discrete time and peak concentration.

The concentration in plants from atmospheric transport is evaluated by first calculating the average concentration in the air above the plant during the period of plume passage, as for tritium.

$$C_{acC} = E_a \qquad (8.25)$$

134

where C_{acC} = concentration of carbon-14 in air at the growing location of crop type c (Bq/m^3)

E_a = time-integrated air concentration at usage location a (Equations 5.20 or 5.27), which incorporates T_e, $(Bq\ sec/m^3)$

The concentration fixed in the plant leaves during this period is in equilibrium with this air concentration and is evaluated as follows.

$$C_{ca\,i}(0) = \frac{C_{acC}\ F_{Cc}\ E_C}{P_C} \tag{8.26}$$

where $C_{cai}(0)$ = concentration in the plant at the time of harvest for crop c from airborne deposition (Bq/kg wet weight)

F_{Cc} = fraction of carbon in crop type c (dimensionless)

P_C = concentration of carbon in air (kg/m^3)

E_C = equilibrium factor for carbon (dimensionless).

The equilibrium factor is evaluated as described above and by the following equation.

$$E_C = \frac{T_{pp}}{T_{gc}\ 24} \tag{8.27}$$

where T_{pp} = period of plume passage, assumed equal to T_e (hr)

T_{gc} = growing period for crop type c (d)

24 = units conversion factor (hr/d).

The plant concentration from irrigation with ^{14}C contaminated water is based on the assumption that no more than 10% of the carbon in a plant comes from root uptake from soil and that no carbon is taken up from water on the plant leaves. Also, no more than 1% of soil is assumed to be carbon. All carbon entering the plant is assumed to be fixed with no subsequent loss. The irrigation deposition rate to soil is used to estimate the ^{14}C concentration in soil at the time of deposition. The deposition is assumed to occur just prior to the harvest so there is no loss of ^{14}C from soil before harvest. This soil concentration is then used to estimate the plant concentration from root uptake. The deposition onto soil via irrigation is modeled as follows.

$$C_{scC}(0) = \frac{C_{wC}\ IR_w\ T_w}{P_3} \tag{8.28}$$

where $C_{scC}(0)$ = concentration of ^{14}C in soil used for crop type c at the time of contamination deposition from irrigation water (Bq/kg soil)

C_{wC} = average water concentration of ^{14}C in irrigation water, over the time of use of the contaminated water (Bq/L)

IR_w = irrigation rate (L./m^2 sec)

T_w = time of plume passage (s)

P_3 = areal soil density of surface soil (kg/m^2).

The average water concentration is evaluated using Equation (6.3).

The plant is assumed to be in equilibrium with this soil concentration using the assumptions mentioned above, as follows.

$$C_{cwC}(0) = \frac{C_{scC}(0)\, 0.1\, F_{cC}}{0.01} \qquad (8.29)$$

where $C_{cwC}(0)$ = concentration on the plant at the time of harvest for crop c from irrigation water deposition (Bq/kg wet weight)

0.1 = fraction of carbon in a plant that is assumed to come via roots (dimensionless)

0.01 = fraction of soil that is carbon (kg C in soil/kg soil)

F_{Cc} = fraction of carbon in crop type c (dimensionless).

There is assumed to be no loss of ^{14}C from the plant after harvest. Therefore, the harvest concentration persists throughout the consumption period.

The concentration of ^{14}C in animal products is based on animal ingestion of contaminated feed (carbon uptake via drinking water is negligible). The feed concentrations are estimated using Equation (8.26) or (8.29) with parameters defined for the feed crop. The animal product concentration is evaluated as follows.

$$C_{awC}(0) = F_{Ca} \frac{\sum_{f=1}^{N_{fa}} C_{fwC}\, U_{af}\, d_{af}}{\sum_{f=1}^{N_{fa}} F_{Ca}\, U_{af}} \qquad (8.30)$$

where $C_{awC}(0)$ = concentration of ^{14}C in animal product a at time of harvest (Bq/kg)

F_{Ca} = fraction of carbon in animal product a (dimensionless)

C_{fwC} = concentration of ^{14}C in animal feed type f at time of animal feed consumption, immediately after contamination (Bq/kg wet weight)

U_{af} = daily intake rate for animal type a of feed type f (kg/d)

d_{af} = fraction of animal type a feed type f intake that is contaminated (dimensionless)

F_{Cf} = fraction of carbon in animal feed type f (dimensionless)

N_{fa} = number of feed crops eaten by animal type a.

There is assumed to be no loss of carbon-14 after animal products production, so the production concentration persists throughout the consumption period.

9.0 CHRONIC EXPOSURE MODULE

The chronic exposure module provides estimates of exposure media concentrations resulting from groundwater, surface water, and airborne contamination pathways. Exposures are treated as continuous and constant over an extended time period (a year or longer) with consideration of the time variation in air and water concentrations. In this section, the communication interfaces are described first, followed by the exposure pathway models for external exposure, ingestion exposure, and inhalation exposure.

The chronic exposure module uses as input radionuclide concentrations in air and water, as generated by the transport models or from user defined input. The output from the module is the radionuclide concentration in various exposure media (air, crops, animal products, soil, aquatic foods, etc.). The exposure pathways considered by the chronic module are indicated in Table 9.1. Model details are given in following sections.

Table 9.1 Exposure Pathways for the Chronic Terrestrial and Aquatic Module

Transport Mode	Exposure Pathways	Exposure Route
atmosphere	air	inhalation
	soil resuspension	inhalation
	soil ingestion	ingestion
	immersion in air	external
	ground exposure	external
	food crops	ingestion
	animal products	ingestion
groundwater	drinking water	ingestion

9.1 COMMUNICATION INTERFACES

The input files for the chronic exposure module are the global input data file (GID), the atmospheric concentration file (ACF), the water concentration file (WCF), and three auxiliary data communication files (radionuclide master date library, food transfer factor data file, aquatic bioaccumulation data file). The communication interfaces are indicated in Figure 9.1. The atmospheric concentration file (ATO) is generated by the atmospheric transport module. The water concentration file (WCF) is generated by the surface water module (or other external program that is capable of generating the water concentration file information). The GID file section for the chronic exposure module is generated by the user interface program. It contains information describing the scope of the analysis and all user-provided input parameters for an analysis. The structure and content of the files are given in Appendix A and B.

The output from the chronic terrestrial and aquatic pathway module is the concentration in various media to which individuals or populations are exposed. Along with each concentration, the duration of exposure is also provided, representing the period of integration for the particular pathway. This information is provided in a primary data communication file, the exposure pathway media concentration output file (EPF).

9.2 SOIL MODEL

The soil model used with the chronic exposure model is described in this section. This model allows calculation of surface soil concentrations as a function of time with consideration of: 1) leaching from surface soil, 2) deposition from air to surface soil, 3) irrigation deposition from water to surface soil, and 4) loss from surface soil from plant harvest. The soil model is applied separately for each exposure pathway allowing different soil concentrations to be used to evaluate each exposure pathway. For example, different soil concentrations can be defined for leafy vegetable crops consumed directly by humans, and for forage crops used by milk animals.

The general soil model is illustrated in Figure 9.2. This figure shows the compartment considered in the model, the surface zone. The surface soil is the portion on which deposition from the atmosphere and irrigation occurs, and that from which resuspension occurs. Radionuclides may be lost from the surface soil through harvest removal, radiological decay, and leaching out of the surface soil layer. All losses from the surface zone (harvest removal or leaching) are assumed to leave the system.

The soil model allows evaluation of the soil concentration over the intake period, accounting for prior atmospheric deposition and prior irrigation water deposition. It is assumed that the time of prior deposition from air and water is less than or equal to the time of start of intake. The soil model then evaluates the soil concentration at the start of the intake period. After the start of intake, the soil model is used to follow the change in soil compartment concentrations as intake is evaluated.

The deposition from prior years of deposition (air and water) is evaluated using atmospheric deposition and water concentration data provided as a function of time. The analysis is performed on an annual basis, using average atmospheric deposition and water concentrations for each year. The models and sub-models defined in the following section are applied on an annual basis as indicated by the time period parameter, T_{yr}, representing a one-year time period.

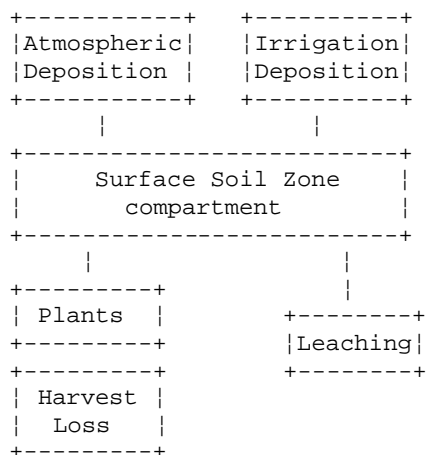

Figure 9.2 Chronic Module Soil Model

141

The model is defined by a differential equation that describes the change of concentration in surface soil as a function of time. The differential equation for the soil model compartment is defined in terms of the amount of each radionuclide chain member present in units of atoms. This representation is used for ease of understanding and ease of solving the equations. The final solutions are evaluated using the radioactive decay-chain processor described in Appendix C. The general solutions presented in that appendix are given in terms of atom units and activity units. For chronic releases, initial amount in the surface soil is set to zero. The decrease from harvest is modeled as a step function following the time of harvest and does not appear in the differential equation for the surface zone. The differential equation for chronic releases for the surface soil zone is as follows:

$$\frac{d\ A_i(t)}{d\,t} = (R_{b\,i} + R_{a\,i}) - (\lambda_{Li} + \lambda_i)\ A_i \tag{9.1}$$

where $A_i(t) =$ amount of radionuclide i in the surface soil zone at time, t (atoms)

Rbi = rate of input from irrigation water (atoms /y)

Rai = rate of input from atmospheric depostion (atoms/y)

$\lambda_i=$ rate constant for radioactive decay of radionuclide i (y^{-1})

λ_{Li} = rate constant for leaching of radionuclide from the surface soil zone (y^{-1}).

Various aspects of the soil model are described in the following subsections. The first section describes definition of air and water deposition during a year for chronic releases. The remaining sections describe estimation methods for the transfer rate constants defined for the soil model.

9.2.1 Activity from Air and Water Deposition

For chronic release analyses the differential equation for surface soil includes terms for deposition from air and irrigation water. The initial concentrations are set to be zero. The amount at the end of a year is evaluated based on the amount present at the beginning of a year plus the amount deposited during the year. In the exposure pathway models that follow, the amount present during a year is composed of two terms: 1) the average amount present during the year from prior years' depositions, and 2) the average amount present from deposited during the year. The average amount present from prior years' contributions is represented by the term $C_{si}(T_{yr})$ with units of Bq/m^2. This amount is evaluated from the amount present at the end of the prior year (corrected as necessary according to soil model transfers), and accounting for radioactive decay and losses during the year. These evaluations are made using the decay processor described in Appendix C. The deposition during the current year is evaluated as defined for each exposure pathway.

9.2.2 Leaching from the Surface Soil Zone

Removal from the surface soils through leaching into deeper soils is treated by means of a soil removal rate constant. For surface soils the rate constant, λ_{si}, is a correction for long-term leaching of deposited radionuclides out of the surface soil (rooting and resuspension zones). The values for λ_{si} are calculated using the formula of Baes and Sharp (1981):

$$\lambda_{si} = \frac{10^{-2}\ (P + I - E)}{d_s\ \theta_s\ \left[1 + \frac{10^3\ 10^{-6}\ \rho_s}{\theta_s}\ Kd_{si}\right]} \tag{9.2}$$

where λ_{si} = removal rate constant for activity of radionuclide i in the surface soil layer (y^{-1})

$\quad\quad$ P = total annual precipitation (cm/y)

$\quad\quad$ I = total irrigation rate (cm/y)

$\quad\quad$ E = total evapotranspiration rate (cm/y)

$\quad\quad$ ρ_s= surface soil bulk density (kg/m^3)

$\quad\quad$ θ_s= surface soil volumetric water content (mL/cm^3)

$\quad$ Kd_{si} = surface soil distribution coefficient for radionuclide i (mL/g)

$\quad$ 10^{-2} = units conversion factor (m/cm)

$\quad$ 10^3 = units conversion factor (g/kg)

$\quad$ 10^{-6} = units conversion factor (m^3/ml)

9.2.3 Loss by Harvest

Loss of activity from the surface soil zone is modeled as a step function applied at the end of each calculational year. The amount of loss is calculated from the plant concentration at harvest, the annual plant yield, and the soil concentrations at harvest. The calculation is represented by the following equation.

$$C_{si}(t_+) = C_{si}(t_-)\left[\left(C_{si} - C_{ci}(Th_c)\ Y_c\right)/C_{si}\right] \tag{9.3}$$

where $C_{si}(t_+)$ = surface soil concentration at soil location s for radionuclide i after correction for harvest removal at time t (Bq/m^2)

$C_{si}(t.)$ = surface soil concentration at soil location s for radionuclide i before correction for harvest removal at time t (Bq/m^2)

$C_{ci}(Th_c)$= crop c concentration for radionuclide i at time of harvest (Bq/kg)

Y_c = annual yield of crop c (kg/m^2)

The multiplicative term represents the average fraction of the contaminant in soil to that in crops over the year; this term is used rather than a simple subtraction of amount harvested because, for short-lived radionuclides, the amount harvested over the year may actually be larger than the amount remaining in the soil at the end of the year.

9.3 EXTERNAL EXPOSURE PATHWAYS

External exposures from atmospheric transport include immersion in air and exposure to contaminated ground following deposition from air. External exposure from groundwater transport involves ground contamination from irrigation deposition. External exposure from surface water transport includes ground contamination from irrigation deposition, swimming in contaminated water, boating on contaminated water, and exposure to shoreline sediment contaminated by transfer from surface water. Models for evaluating these exposure pathways are provided here.

9.3.1 External Plume Immersion

External exposure from immersion in a plume is evaluated in the atmospheric transport component and provided to subsequent components as the radiation dose (Sv) received during plume passage at specific locations. As such, no models need to be described in this section. The evaluation of radiation dose is performed using the finite dimensions of the plume. However, an alternate method for evaluating external exposure is described here using the semi-infinite plume model, which does not require knowledge of plume dimension. The model uses the average air concentration over the exposure period to estimate dose.

The input parameter for estimation of external exposure to the plume using the semi-infinite plume model is the average air concentration of a radionuclide in the plume, as estimated by the atmospheric transport component, $\chi_{nv} = C_{ai}$ = air concentration for radionuclide i at usage location a (Bq/m^3) from Equations 5.19 or 5.28.

9.3.2 External Ground Exposure

External exposure to contaminated ground is considered for atmospheric transport and deposition, for groundwater and surface water irrigation, and deposition from these sources from prior years' activity.

The exposure parameter for this pathway is the average soil concentration over the year of exposure in units of Bq/m^2. If the exposure parameter is divided by the soil areal density, then

the units are in Bq/kg. The soil concentration used in evaluation of the external exposure is given by the following expression that includes contributions from the two deposition routes (air, and water) plus the concentration present at the start of the year.

$$C_{esi}(T_{yr}) = \left[C_{si}(T_{yr}) + \left[R_{ait} + R_{wit} \right] \frac{1}{\lambda_i \, T_{yr}} \left[T_{yr} - \frac{1 - e^{-\lambda_i \, T_{yr}}}{\lambda_i} \right] \right] / (d_s \, \rho_s) \qquad (9.4)$$

where $C_{esi}(T_{yr})$ = average surface soil concentration at soil location s for radionuclide i including deposition during the year (Bq/kg)

$C_{si}(T_{yr})$ = average surface soil concentration at soil location s for radionuclide i during the current year from material present at the start of the year (Bq/m^2)

R_{ait} = constant deposition rate of radionuclide i from air for year t (Bq/m^2·y)

R_{wit} = constant deposition rate of radionuclide i from water for year t (Bq/m^2·y)

d_s = thickness of soil (m)

ρ_s = density of soil (kg/m^3)

T_{yr} = one year integration period (y).

The terms at the right of Equation (9.4), following the sum of the deposition rates, represent evaluation of the time integral in soil from deposition at a constant rate with accumulation over a one year period. Division by the one-year period provides the average soil concentration during the year. This equation is appropriate when the exposure occurs relatively uniformly over the one-year period.

The deposition rates are defined for each transport route for the current year. The deposition rate from atmospheric deposition (R_{ait}) is taken directly from the atmospheric transport output file. For waterborne transport and irrigation deposition (from groundwater or surface water), the deposition rate to soil is given as follows.

$$R_{wit} = C_{wi}(T_{yr}) \, IR_w \, 25.4 \qquad (9.5)$$

where R_{wit} = constant deposition rate of radionuclide i from water for year t at water location w (Bq/m^2/y)

$C_{wi}(T_{yr})$ = average annual concentration of radionuclide i in water used for irrigation during a year at water location w (Bq/L)

IR_w = irrigation rate at water location w (in/y)

25.4 = units conversion factor (L per m^2·in)

The irrigation rate is the total amount of water applied, averaged over the entire year.

9.3.3 Recreational Swimming Immersion

Individuals who swim in contaminated surface water may receive external exposure from immersion in the water. The output exposure parameter is the time-integral average of water concentration over the current year, with consideration of the time spent in recreational swimming. The average water concentration is read from the water concentration file (WCF) for the recreational swimming location (Equation 6.7).

9.3.4 Recreational Boating Exposure

Individuals who boat on contaminated surface water may receive external exposure from the water. The exposure is evaluated as the time-integral of water concentration over the current year, with consideration of the time spent in boating. The water concentration is evaluated as for the swimming exposure pathway as per Equation (6.7).

9.3.5 Recreational Shoreline Exposure

Individuals involved in recreational shoreline activities (sun bathing, fishing, etc.) along contaminated surface water may receive external exposure from the sediment contaminated by the water. The sediment concentration at the end of a year is evaluated from the water concentration (Equation 6.7) as follows.

$$C_{sri}(T_{yr}) = \frac{TC \, C_{ri}(T_{yr}) \, (1 - e^{-l_i \, T_{yr}})}{l_i} \tag{9.6}$$

where $C_{sri}(T_{yr})$ = concentration of radionuclide i in sediment after one year of accumulation, from deposition on the shoreline at recreational water usage location r (Bq/m^2)

$\quad\quad$ TC = transfer rate constant from water to sediment (L/m^2/y)

$\quad\quad$ $C_{ri}(T_{yr})$ = average (constant) annual water concentration for radionuclide i at recreational water usage location r (Bq/L)

$\quad\quad$ T_{yr} = one year integrating period for deposition to sediments (y).

The transfer rate constant describes the rate of transfer of material from water to shoreline sediment. The value of the transfer constant was derived for several radionuclides by using data obtained from analyzing water and sediment samples taken from the Columbia River between Richland, Washington, and the river mouth, and from Tillamook Bay, Oregon, 75 km south of the river mouth (Nelson 1965; Toombs and Cutler 1968). This data was analyzed by Soldat,

Robinson, and Baker (1974) to derive a value of 2.54×10^4 in units of $L/m^2/y$. (This is more significant figures than used in the original reference, but the original value of 10^2 in other units has been retained for historical consistency.)

The recreational water concentration parameter, $C_{ri}(T_{yr})$, is provided by the waterborne transport component (Equation 6.7).

The exposure is evaluated as the time-integral of shoreline sediment concentration over the current year, with consideration of the time spent on the shoreline. The external exposure parameter is evaluated by determination of the average sediment concentration during a year, as

$$C_{sri}(T_{yr}) = \int_0^{T_{yr}} C_{sri}(t)\, dt \; / \; (T_{yr}\, d_{sed}\, \textbf{r}_{sed}) \qquad (9.7)$$

where $C_{sri}(T_{yr}) =$ shoreline sediment time integral of exposure for radionuclide i evaluated at the recreational usage location r (Bq/kg)

$\quad d_{sed} \;\; = \;\;$ thickness of shoreline sediments (m)

$\quad \rho_{sed} \;\; = \;\;$ density of shoreline sediments (kg/m^3)

$\quad T_{yr} \;\; = \;\;$ one year exposure period (y).

For cases where there is a period of deposition during prior years but no current release, the above time integral includes consideration of decay of the accumulations from prior years, using the decay processor described in Appendix C.

9.4 INGESTION EXPOSURE PATHWAYS

Ingestion exposures from atmospheric transport include ingestion of farm products and inadvertent ingestion of soil. Farm products include leafy vegetables, other vegetables, cereal grains, fruit, cow's milk, beef/meat, poultry, and eggs (poultry). Ingestion exposure from groundwater transport includes ingestion of drinking water, ingestion of farm products, and inadvertent ingestion of soil contaminated by irrigation water. Ingestion exposure pathways from surface water transport include ingestion of drinking water, ingestion of farm products, inadvertent ingestion of soil contaminated by irrigation water, and ingestion of aquatic products. Four types of aquatic foods are considered: fish, mollusks, invertebrates, and water plants.

9.4.1 Terrestrial Farm Product Ingestion

The terrestrial farm product pathways include leafy vegetables, other vegetables, cereal grains, fruit, cow's milk, beef/meat, poultry, and eggs (poultry). The output parameter for these pathways is the average concentration of radionuclides in the food product at the time of consumption.

The terrestrial farm products may be contaminated by either atmospheric deposition or irrigation deposition onto plants and soil, resuspension and deposition onto plant surfaces, or by animal consumption of contaminated water. The plants may also be contaminated from root uptake of residual surface soil contamination. The discussion of terrestrial farm product pathways begins with a discussion of methods for determining the air, soil, and water concentrations that form the starting point for the calculation. The farm crops are then discussed, followed by the farm animal products.

9.4.1.1 Terrestrial Media Concentrations

Evaluation of farm product concentrations requires use of radionuclide depositions from air, soil, and water. The air deposition used for the terrestrial farm product pathways is the deposition at the location of production of the farm product. This deposition is represented by an average value based on output of the atmospheric transport component. The annual average deposition rate is evaluated as the time integral of the deposited activity for deposition at a constant rate. The differential equation describing the deposition and accumulation is as follows.

$$\frac{d\ C_{ai}(t)}{d\,t} = R_{ait} - \lambda_i\,C_{ai}(t) \tag{9.8}$$

where $C_{ai}(t)$ = deposited amount from air to soil or plants at location a for radionuclide i as a function of time (Bq/m^2)

   R_{ait} = constant deposition rate of radionuclide i from air at location a $(Bq/m^2\ y)$

   λ_i = radiological decay constant for radionuclide i (y^{-1}).

The atmospheric deposition rate is the total deposition rate and is the sum of the dry deposition and wet deposition components (R_{aitd} and R_{aitw}, respectively).

The double time-integral of this equation is evaluated and divided by one year to give the annual average deposition per unit area. This parameter is used to evaluate the total amount deposited on plants and soil. The deposition is taken directly from the atmospheric transport output file summing over the wet and dry deposition components.

Deposition of radionuclides onto plants and soil from use of contaminated water for irrigation is evaluated in a similar manner to atmospheric deposition, with the deposition rate for water represented by the parameter R_{wit}, for water usage location w. The deposition rate is used in Equation (9.8) in place of the atmospheric deposition rate, R_{ait}. The deposition rate from water is represented as given previously by Equation (9.5) in units of $Bq/m^2\cdot y$.

The soil concentration is used for estimation of resuspension and re-deposition of activity onto plant surfaces, and for estimation of root uptake to plants. The concentration during the year is calculated as the sum of the surface soil concentration from the soil model (see Section 9.2), $C_{si}(T_{yr})$, and contributions from the three deposition pathways just mentioned. The soil

concentration can be expressed as follows, in which the contribution from deposition is represented by a time integral of deposition over the current one-year period.

$$C_{ci}(T_{yr}) = C_{si}(T_{yr}) + \frac{R_{ait} + R_{wit}}{l_i \, T_{yr}} \left[T_{yr} - \frac{1 - e^{-l_i \, T_{yr}}}{l_i} \right] \qquad (9.9)$$

where $C_{ci}(T_{yr})$ is the average concentration of radionuclide i in farmland soil for crop type c during the current year (Bq/m^2), $C_{si}(T_{yr})$ is the average concentration during the current year of radionuclide i in surface soil at location s (where crop c is grown) for deposition from prior years (Bq/m^2), and other terms are as previously defined.

9.4.1.2 Terrestrial Farm Crop Concentrations

The concentration in plants at the time of harvest is evaluated as the sum of contributions from deposition onto plant surfaces, plus uptake through the roots. The contribution from deposition includes deposition directly onto plant surfaces from the air (dry and wet deposition), deposition from material resuspended from soil ,and material deposited from irrigation water. Weathering losses from plant surfaces prior to harvest is also included. The plant concentration at harvest from deposition pathways is evaluated as follows.

$$C_{dci}(T_{yr}) = \left[R_{aitd} \, r_{dc} + R_{aitw} \, r_{wc} + 3.15\,E\,7 \, C_{ci}(T_{yr}) \, RF_c \, Vd_i \, r_{dc} + R_{wit} \frac{12 \, r_{ic}}{M_c} \right]$$
$$\frac{Tv_c}{B_c} \left[\frac{1 - e^{-\lambda_{ei} \, Tg_c \, 2.74\,E-3}}{\lambda_{ei}} \right] \qquad (9.10)$$

where $C_{dci}(T_{yr})$ =   concentration of radionuclide i on plant type c at harvest from deposition processes for a one year period (Bq/kg wet weight)

T_{yr} = one year exposure period (y)

r_{dc} = interception fraction from airborne dry deposition for plant type c (dimensionless)

r_{wc} = interception fraction for airborne wet deposition to plant type c (dimensionless)

$C_{ci}(T_{yr})$ = average concentration of radionuclide i in farmland soil for crop type c for the current one year period (Bq/m^2)

RF_c = resuspension factor for crop soil (m^{-1})

Vd_i = deposition velocity of radionuclide i (m/s)

12 = months per year (mo/y)

r_{ic} = interception fraction for irrigation deposition to plant type c (dimensionless), generally equal to r_{wc}

M_c = irrigation period for plant type c (mo)

Tv_c = translocation factor for plant type c (dimensionless)

B_c = total standing biomass for plant type c (kg wet weight/m^2)

λ_{ei} = effective loss rate constant from plant surfaces representing weathering and radioactive decay for radionuclide i (y^{-1})

$\lambda_{ei} = \lambda_{wi} + \lambda_i$

λ_{wi} = weathering rate constant for crops for radionuclide i (y^{-1})

Tg_c = crop growing period for plant type c (d)

$3.15E7$ = units conversion factor (sec/y)

$2.74E\text{-}3$ = units conversion factor (y/d).

The plants are also contaminated from root uptake from surface soil. The plant concentration at harvest from root uptake pathways is evaluated as follows.

$$C_{rci}(T_{yr}) = \frac{C_{ci}(T_{yr})\ RP_{sc}\ Bv_{ci}\ f_c}{P_3} \qquad (9.11)$$

where $C_{rci}(T_{yr})$ = concentration of radionuclide i in crop type c from root uptake pathways for a one year period (Bq/kg wet weight)

Bv_{ci} = concentration ratio for root uptake of radionuclide i in crop type c (Bq/kg dry plant per Bq/kg dry soil)

f_c = dry-to-wet ratio for plant type c (kg dry plant/kg wet plant)

P_3 = areal soil density of farmland soil (kg/m^2)

RP_{sc} = fraction of plant type c roots in surface soil zone (dimensionless).

The total concentration in the plant at the time of harvest is the sum of the contributions from deposition pathways and root uptake pathways.

150

$$C_{hci}(T_{yr}) = C_{dci}(T_{yr}) + C_{rci}(T_{yr}) \qquad (9.12)$$

where $C_{hci}(T_{yr})$ is the concentration in plant type c at harvest for a one year period (Bq/kg wet weight) and other terms are as previously defined.

The concentration in crops at the time of consumption is evaluated by accounting for decay between harvest and consumption. The holdup delay time defines this time period. The calculation is performed using the decay processor (see Appendix C). The calculation is represented for the parent radionuclide as follows.

$$C_{csi}(T_{yr}) = C_{hci}(T_{yr}) \, e^{-\lambda_i \, Th_c \, 2.74E\text{-}3} \qquad (9.13)$$

where $C_{csi}(T_{yr}) =$ concentration of radionuclide i in crop type c at location s at the time of consumption over a one year period (Bq/kg wet weight)

Th_c =   holdup delay time between harvest and consumption for crop type c (d)

λ_i =   radiological decay constant for radionuclide i (y^{-1}).

9.4.1.3 Terrestrial Farm Animal Product Concentrations

Pathways by which animal products may become contaminated include animal ingestion of plants, water, and soil. The concentration in feed plants is evaluated in a similar manner to the food crop calculations as defined in Equations (9.10) through (9.13), with parameters defined for animal feed crops in place of human food crops. The feed crop concentration at the time of animal feeding, $C_{cfi}(T_{yr})$, is evaluated using Equation (9.13) with the holdup delay time representing the time between harvest and consumption by animals. The water concentration is the value supplied on the input file, $C_{wi}(T_{yr})$, as the average concentration over the current year. The soil concentration is the average surface soil concentration for the year given by the parameter, $C_{ai}(T_{yr})$, for animal product, a, and radionuclide i in units of Bq/m^2, evaluated using Equation (9.9). The concentration in an animal product at the time of harvest (slaughter, milking, or egg collection), is evaluated as follows.

$$C_{hai}(T_{yr}) = Fa_i \left[C_{wi}(T_{yr}) \, d_{aw} \, U_{aw} + C_{ai}(T_{yr}) \, d_{as} \, U_{as} + \sum_{f=1}^{N_{af}} C_{fi}(T_{yr}) \, d_{af} \, U_{af} \right] \qquad (9.14)$$

where $C_{hai}(T_{yr})$ = concentration of radionuclide i in animal product a at harvest of the animal product for a one year period (Bq/kg)

T_{yr} =   one year exposure period (y)

Fa_i = transfer coefficient that relates daily intake rate by an animal to the concentration in an edible animal product a (Bq/L milk per Bq/d for milk and Bq/kg meat per Bq/d for meat)

$C_{wi}(T_{yr})$ = average concentration of radionuclide i in water consumed by animals for a year (Bq/L)

$C_{ai}(T_{yr})$ = average concentration of radionuclide i in soil consumed by animals for a year (Bq/kg dry soil)

$C_{cfi}(T_{yr})$ = concentration of radionuclide i in animal feed type f at time of consumption for a one year period (Bq/kg wet weight)

d_{aw} = fraction of animal type a water intake that is contaminated (dimensionless)

U_{aw} = daily water intake rate for animal type a (L/d)

d_{as} = fraction of animal type a soil intake that is contaminated (dimensionless)

U_{as} = daily soil intake rate for animal type a (kg/d) [currently set to zero]

N_{af} = number of feed types, f, fed to animal type a

d_{af} = fraction of animal type a feed type f intake that is contaminated (dimensionless)

U_{af} = daily feed intake rate for animal type a of feed type f (kg/d)

and other terms are as previously defined.

The concentration in animal products at the time of consumption is evaluated by accounting for decay between harvest and consumption. The holdup delay time defines this time period. The calculation is performed using the decay processor (see Appendix C). The calculation is represented for the parent radionuclide as follows.

$$C_{asi}(T_{yr}) = C_{hai}(T_{yr})\, e^{-\lambda_i\, Th_a\, 2.74E\text{-}3} \qquad (9.15)$$

where $C_{asi}(T_{yr})$ = concentration of radionuclide i in animal product a at usage location s at the time of consumption for a one year period (Bq/kg wet weight)

Th_a = holdup delay time between harvest and consumption for animal product a (d)

λ_i = radiological decay constant for radionuclide i (y^{-1}).

152

9.4.1.4 Interception Fraction

The interception fraction for a given vegetation type is a factor that accounts for the fact that not all of the material deposited within a unit area will end up on vegetation surfaces. The fraction of the total deposition that initially resides on plants is the interception fraction. Interception fractions are needed for sprinkler irrigation deposition, and for dry and wet deposition from air.

The interception of material in irrigation water, r_{ic}, is not well studied. Thus, a default value of 0.25 is used for all materials deposited on all plant types by irrigation.

An empirical relationship between biomass and interception fraction from atmospheric dry deposition was originally suggested by Chamberlain (1967). This model has been expanded by Pinder, Ciravolo, and Bowling (1988) for grasses and other species. The following form of the equation is used for grasses, leafy vegetables, and grains:

$$r_{dc} = 1 - e^{-2.9 \ Y_c \ f_c} \tag{9.16}$$

where r_{dc} =   interception fraction for atmospheric dry deposition to crop type c (dimensionless)

   Y_c =   standing biomass of the growing vegetation for crop type c (kg wet weight/m^2)

   f_c =   dry-to-wet weight biomass ratio for crop type c (kg dry weight per kg wet weight).

A similar equation is used for fruits and other vegetables:

$$r_{dc} = 1 - e^{-3.6 \ Y_c \ f_c} \tag{9.17}$$

where terms are as previously defined. The dry-to-wet ratio is required because the Pinder formulations are given in terms of dry biomass. This formulation results in the need to define the growing biomass, as well as the harvested yield (for use with the harvest removal term defined in Section 9.2.7). The values for biomass and dry-to-wet ratio are given in Table 9.2.

The interception fraction for wet deposition is evaluated as a function of the rainfall rate and standing biomass based on experimental observations of Proel and Hoffman (1993). The data by Proel and Hoffman were used to develop relationships for anions, cations, and for insoluble particles. For anions, such as iodide and sulfate, the interception fraction is evaluated as follows:

$$r_{wc} = 2.3\, Y_c\, f_c\, R^{-0.92} \tag{9.18}$$

where r_{wc} = interception fraction from wet deposition to crop type c (dimensionless)

      Y_c = standing biomass of the growing vegetation for crop type c (kg wet weight/m^2)

      f_c = dry-to-wet weight biomass ratio for crop type c (kg dry weight per kg wet weight).

      R = rainfall rate (mm/d)

For particles, Proel and Hoffman presented the following relationship based on experiments using microspheres.

$$r_{wc} = 2.95\, Y_c\, f_c\, R^{-0.191} \tag{9.19}$$

where terms are as previously defined.

Table 9.2.   Harvested Yield, Standing Biomass, and Ratio of Dry to Wet Vegetation Used in Interception and Harvest Removal Models

Category	Harvested[a] Yield (wet) for Soil Removal	Standing[b] Biomass (wet) for Interception	Dry-to-Wet[c] Ratio for Interception
Leafy Vegetables	2.0	2.0	0.10
Other Vegetables	4.0	2.0	0.25
Grain	0.6	0.8	0.18
Fruit	2.0	3.0	0.18
Meat: Forage/Hay	2.0[d]	1.0	0.20
Meat: Grain	0.6	0.8	0.18
Poultry & Eggs:			
Grain	0.6	0.8	0.18
Milk: Fresh Forage	3.0[d]	1.5	0.20
Milk: Hay	2.0[d]	1.0	0.20

(a)   Adapted from data in Shor, Baes, and Sharp (1982) for the Washington counties of Benton, Franklin, and Yakima; these represent highly-productive agriculture.

(b)   Derived from data in Shor, Baes, and Sharp (1982), Strenge, Bander, and Soldat (1987), or Napier et al. (1980).

(c)   Adapted from Till and Meyer (1983), Section 5.

(d)   Multiple cuttings.

9.4.1.5 Resuspension Factor

The resuspension factor relates the radionuclide concentration in soil (per unit area) to the concentration in air. The resuspension factor for food crop and animal product pathways is representative of conditions on farmland, which may be different from the resuspension factor for the inhalation exposure pathway. Farmland would be expected to be tilled and have soil generally looser than soil for the general residential exposure situations.

9.4.1.6 Translocation Factor and Weathering Loss

Material deposited on plant surfaces is subject to absorption and removal processes. The translocation factor indicates the fraction of total deposition to plant surfaces that is incorporated into edible parts of the plant. A value of 1 is assumed for leafy vegetables and forage crops, and 0.1 for all other vegetation.

Losses from plant surfaces are represented by a weathering rate constant, λ_{wi}. The rate constant is based on a weathering half time of 14 days.

9.4.2 Aquatic Food Ingestion

Aquatic food products may become contaminated when grown in contaminated surface waters. The aquatic food pathways include ingestion of fish, crustaceans, mollusks, and aquatic plants. The concentration in an aquatic food is based on the average surface water concentration for the current year, as follows.

$$C_{hqi}(T_{yr}) = C_{wi}(T_{yr}) \, B_{qi} \tag{9.20}$$

where $C_{hqi}(T_{yr})$ =   concentration of radionuclide i in aquatic food type q at time of harvest (Bq/kg)

       B_{qi} =   bioaccumulation factor for radionuclide i in aquatic food type q (Bq/kg wet fish per Bq/L water).

The concentration at the start of the consumption period is evaluated accounting for decay during holdup as follows.

$$C_{fwi}(T_{yr}) = C_{hqi}(T_{yr}) \, e^{-\lambda_i \, Th_q \, 2.74E\text{-}3} \tag{9.21}$$

where $C_{fwi}(T_{yr})$ =   concentration of radionuclide i in aquatic food type q at water location w the time of consumption (Bq/kg wet weight)

       Th_q =   holdup delay time between harvest and consumption for aquatic food type q (d)

       λ_i =   radiological decay constant for radionuclide i (y^{-1}).

This calculation is performed using the chain decay processor described in Appendix C.

Individuals who swim in contaminated surface water may inadvertently ingest some of the water. The output exposure parameter is the time-integral average of water concentration over the current year, with consideration of the time spent in recreational swimming. The average water concentration is read from the water concentration file (WCF) for the recreational swimming location (Equation 6.7).

9.4.3 Drinking Water Ingestion

Exposure to contaminated drinking water may occur from groundwater or surface water sources. The input to the pathway is the average water concentration from the input file, $C_{wi}(T_{yr})$. The output for the pathway is the water concentration at the location of consumption corrected (if necessary) for removal of contamination in a water treatment plant and for decay in transit from the pumping station to the usage location. The water concentration at the point of consumption is evaluated as follows.

$$C_{dwi}(T_{yr}) = C_{wi}(T_{yr}) \, TF_i \, e^{-\lambda_i Th_w \, 2.74E\text{-}3} \tag{9.22}$$

where $C_{dwi}(T_{yr})$ = concentration of radionuclide i in water at water usage location w at the time of consumption (Bq/L)

TF_i = water treatment purification factor giving the fraction of radionuclide i remaining in the water after treatment (dimensionless)

λ_i = radiological decay constant for radionuclide i (y^{-1})

Th_w = holdup time between the water intake plant and the water point of water use (d)

$2.74E\text{-}3$ = units conversion factor (y/d).

This calculation is performed using the chain decay processor described in Appendix C.

This concentration is also used in the estimation of ingestion intake from inadvertent ingestion during showering.

9.4.4 Inadvertent Soil Ingestion

The inadvertent ingestion of soil is evaluated for all media (atmospheric deposition to soil, groundwater as a contaminated medium for irrigation, and surface water as a contaminated medium for irrigation). The average concentration in soil over the current one year period is evaluated as described in Section 9.2.

The exposure parameter for ingestion of soil is the average soil concentration (Bq/kg soil) evaluated as follows.

$$C_{dsi}(T_{yr}) = \frac{10^3}{10^4 \, r_s \, d_s}\left[C_{si}(T_{yr}) + \frac{R_{ait} + R_{wit}}{l_i \, T_{yr}}\left(T_{yr} - \frac{1 - e^{-l_i \, T_{yr}}}{l_i}\right)\right] \qquad (9.23)$$

where $C_{dsi}(T_{yr})$ = average concentration at soil location s for radionuclide i in soil consumed during the current year (Bq/kg)

$C_{si}(T_{yr})$ = average surface soil concentration at soil location s for radionuclide i during the current year (Bq/m^2)

ρ_s = density of surface soil (g/cm^3)

d_s = thickness of surface soil layer (cm)

10^4 = units conversion factor (cm^2/m^2)

10^3 = units conversion factor (g/kg)

and other terms are as previously defined. The inclusion of deposition terms from air and water is evaluated for each location as appropriate to the defined exposure scenario. For example, if no irrigation is used then the irrigation deposition term, R_{wit}, would not be included in the calculation.

9.5 INHALATION EXPOSURE PATHWAYS

Inhalation exposure pathways include direct inhalation of contaminated plumes and inhalation of resuspended activity from soil. Inhalation of radionuclides volatilized from contaminated water may also occur for domestic use situations. These exposure pathways are described in this section. The output parameter for each pathway is the average air concentration over the exposure period (current year).

9.5.1 Inhalation of Air

The output from the atmospheric transport component is the air concentration at specific locations. This concentration represents the average air concentration for exposure via inhalation, Equations 5.19 or 5.26.

9.5.2 Inhalation of Resuspended Soil

The model for inhalation exposure from resuspended activity uses the resuspension factor approach (as described in Section 9.4.1.2). The resuspension factor relates the soil concentration (per unit area) to the air concentration (per unit volume) and has units of m^{-1}. The use of resuspension factors is based on the assumption that the particulate matter in the air has the same activity as the soil at the location. This is represented mathematically as follows.

$$C_{sai}(T_{yr}) = RF_a \left[C_{si}(T_{yr}) + \frac{R_{ait} + R_{wit}}{\lambda_i \, T_{yr}} \left(T_{yr} - \frac{1 - e^{-\lambda_i \, T_{yr}}}{\lambda_i} \right) \right] \tag{9.24}$$

where $C_{sai}(T_{yr})$ = air concentration of radionuclide i at soil resuspension exposure location a for a year (Bq/m^3)

$\quad RF_a$ = resuspension factor for soil exposure locations (m^{-1})

$\quad C_{si}(T_{yr})$ = average surface soil concentration over the current year at the soil exposure location s from material deposited in prior years (Bq/m^2)

and other terms are as previously defined. The inclusion of deposition terms from air and water is evaluated for each location as appropriate to the defined exposure scenario. For example, if no waterborne deposition is present, then the waterborne deposition term, R_{wit}, would not be included in the calculation.

The resuspension factor may be estimated in one of two ways - either by using a time-dependent function developed by Anspaugh et al. (1975) or by means of a mass loading factor. The Anspaugh resuspension factor is given as follows.

$$RF_a = 10^{-4} \, e^{-0.15 \sqrt{t}} + 10^{-9} \tag{9.25}$$

where $\quad 10^{-4}$ = resuspension factor at the time of initial deposition to soil (m^{-1})

$\quad\quad t$ = time after initial deposition of material to soil (d)

$\quad 0.15$ = effective decay constant controlling the availability of material for resuspension $(d^{1/2})$

$\quad 10^{-9}$ = resuspension factor after 17 years (m^{-1}).

The second term in this equation is added based on the assumption that no further measurable decrease in the resuspension factor process occurs after about 17 years, the longest period for which there are data available.

In the implementation, an assumption is made that only the top thin layer of soil is available for resuspension using the Anspaugh method.

The second method for estimating the resuspension factor is to use the atmospheric mass loading of soil in air, as follows.

$$RF_a = \frac{S}{\rho_s \, d_{rs} \, 10^6}$$

(9.26)

where   S = mass loading of soil in air (g/m^3)

ρ_s = surface soil density (g/cm^3).

d_{rs} = thickness of surface soil layer at resuspension location (m). In the code, this is assumed to be the full general surface soil layer; a modification as for the Anspaugh model is not needed.

10^6 = units conversion factor (cm^3/m^3).

9.5.3 Indoor Inhalation of Waterborne Contaminants

Radionuclides in domestic water may be released during household activities that involve heating and use of water. Such activities include showering, clothes washing, dish washing, cooking, and general use of water in which the water is open to room air. Most radionuclides are considered to be non-volatile and their transfer to indoor air would be small. However, volatile radionuclides could be released in sufficient amounts to warrant inclusion in the exposure pathway analysis. Volatile radionuclides of interest include radon, krypton, and elemental tritium. The amount of airborne material can be estimated using a model for indoor air inhalation exposure developed by Andelman (1990). This model applies a volatilization factor to the water concentration to estimate an average indoor air concentration for the inhalation exposure pathway, as follows.

$$C_{vwi}(T_{yr}) = C_{wi}(T_{yr}) \, T_{fi} \, K_r \, e^{-\lambda_i \, Th_w \, 2.74E\text{-}3}$$

(9.27)

where $C_{vwi}(T_{yr})$ = concentration of radionuclide i in indoor air from volatilization from domestic water for year t (Bq/m^3)

TF_i = water treatment purification factor giving the fraction of radionuclide i remaining in the water after treatment (dimensionless)

K_r = Andelman volatilization factor for radionuclide pollutants (L/m^3)

λ_i = radiological decay constant for radionuclide i (y^{-1})

Th_w = holdup time between the water intake plant and the point of water use (d)

2.74E-3 = units conversion factor (y/d).

The numerical value suggested for the volatilization factor is 0.1 L/m^3 for ^{222}Rn. This value could reasonably be used for other noble gases and elemental tritium. For other radionuclides, significant volatilization is not expected. An exception would be if the radionuclide were associated with a volatile chemical (as for a tagged tracer chemical). In this case the volatilization factor of 0.5 may be appropriate, as suggested by Andelman for volatile chemicals. A minimum value for the volatilization factor can be estimated from a recent study on the behavior of hexavalent chromium in tapwater (Finley et al. 1996). Measurements of the airborne concentration of chromium were made within a shower stall in which contaminated water was sprayed against a mannequin. The results indicated that the air concentration of chromium could be approximated by multiplying by a factor of 3.0×10^{-5}, with concentration units as expressed for Equation (9.33). This suggests that a minimum value to use in place of the Andelman volatilization factor would be 3.0×10^{-5} (L/m^3) for non-volatile radionuclides.

Indoor air is assumed to contain contaminants that have infiltrated from outdoors. The value calculated for $C_{vwi}(T_{yr})$ is then added to the outdoor air concentration calculated using Equations 5.19 or 5.28 to give the total indoor air concentration.

9.6 SPECIAL RADIONUCLIDE MODELS: TRITIUM AND CARBON-14

The behavior of the radionuclides tritium and carbon-14 in exposure pathways is handled in a special manner. The concentrations of tritium or carbon-14 in environmental media (soil, plants, and animal products) are assumed to be related to the specific activity (Becquerels of radionuclide per kilogram of soluble element) in the contaminating medium (air or water). The fractional content of hydrogen or carbon in a plant or animal product is then used to compute the concentration of tritium or carbon-14 in the food product under consideration. The hydrogen contents in both the water and the nonwater (dry) portion of the food product are used when calculating the tritium concentration. The creation of organically-bound tritium in plant and animal products from intake of HTO is also addressed.

For airborne releases, it is assumed that plants obtain all their carbon from airborne carbon dioxide and that animals obtain all their carbon through ingestion of plants. The transfer of ^{14}C from water to plants is difficult to model because plants acquire most of their carbon from the air. Currently available models for ^{14}C uptake by plants from water use specific-activity models relating the activity in the plants directly to the activity in irrigation water. This is extremely conservative in that it assumes that plants receive all of their carbon from water. The model described here is based on the ratio of grams of carbon-14 to grams of total carbon in soil and a correction for the amount of carbon plants obtain from soil.

The special models for ^{3}H as water vapor (HTO) and elemental tritium gas (HT) are described first. The models described are a variant of the model proposed by Peterson and Davis (2002). The ^{14}C models are then described.

9.6.1 Special Tritium Models

Tritiated Water (HTO)

For HTO releases, concentrations in air moisture C_{am} (Bq L^{-1}) are found by dividing the concentration in air (Bq m^{-3}) by the absolute humidity (kg or L m^{-3}).

To estimate HTO concentrations in plant products, it is assumed conservatively that the concentration of HTO in plant water equals 0.9 C_{am} for leafy vegetables and pasture and 0.8 C_{am} for fruit, root crops and other vegetables, and grain. These reduction factors account for dilution from soil water, which has a lower tritium concentration than does air moisture for atmospheric releases and which affects fruit and root crops more than leaves (Table 9.3). OBT concentrations are estimated from a plant water concentration of 0.9 C_{am} for all plant types, since OBT is assumed to form exclusively in the leaves and to be translocated to other plant parts. Then, isotopic discrimination occurring in the formation of OBT (Table 9.4) is assumed conservatively to result in an OBT concentration 0.9 times the concentration of HTO in plant water. Drinking water for animals and people is conservatively assumed to have concentrations of 50% and 10% of air moisture, respectively.

The equation for calculating concentrations of HTO in plant products (Bq kg^{-1} fw) is:

$$C_{pp\_HTO} = RF_{pp}\, C_{am}\, F_{fw\_pp} \tag{9.28}$$

where

RF_{pp} = reduction factor that accounts for low soil water concentrations relative to concentrations in air moisture and varies by vegetable type

The equation for calculating concentrations of OBT in plant products (Bq kg^{-1} fw) is:

$$C_{pp\_OBT} = RF_l\, ID_{pp}\, C_{am}\, F_{dm\_pp}\, W_{eq\_pp} \tag{9.29}$$

where

RF_l = reduction factor for plant leaves

ID_{pp} = isotopic discrimination factor for plant products

Values and definitions for the parameters appearing in Eqns (9.28) and (9.29) for leafy vegetables, fruit, root and other vegetables, grain and pasture are shown in Table 9.3. Values for fresh and dry matter fractions and water equivalent factors were obtained from Geigy (1981).

HTO concentrations in animals are assumed to equal the weighted average tritium concentration of ingested water based on the fraction of water supplied by each source. These sources comprise food (from plant water and digested organically bound molecules) and drinking water.

The concentration of tritium in animal products is calculated from the concentrations in feed and water, as follows.

$$C_{HTOap}(T_{yr}) = F_{Wa} \frac{C_{wH}(T_{yr}) \; U_{wa} \; d_{aw} + \sum_{f=1}^{N_{fa}} C_{cfH}(T_{yr}) \; U_{af} \; d_{af}}{U_{wa} + \sum_{f=1}^{N_{fa}} (F_{fw\_pp} \; U_{af} + F_{dm\_pp} W_{eq\_pp} U_{af})} \qquad (9.30a)$$

where $C_{HTOap}(T_{yr})$ = concentration of tritiated water in animal product a at time of consumption by humans over a one year period (Bq/kg)

$\qquad\qquad F_{Wa}$ = fraction of water in animal product a (dimensionless)

$\qquad\qquad C_{wH}(T_{yr})$ = average concentration of tritium i in water consumed by animal type a over a one year period (Bq/L)

$\qquad\qquad U_{aw}$ = daily water intake rate for animal type a (L/d)

$\qquad\qquad d_{aw}$ = fraction of animal type a water intake that is contaminated (dimensionless)

$\qquad\qquad C_{cfH}(T_{yr})$ = concentration of tritium (the sum of the water and organic portions, estimated as described above) in animal feed type f at time of consumption for a one year period (Bq/kg wet weight)

$\qquad\qquad U_{af}$ = daily intake rate for animal type a of feed type f (kg/d)

$\qquad\qquad d_{af}$ = fraction of animal type a feed type f intake that is contaminated (dimensionless)

$\qquad\qquad N_{fa}$ = number of feed crops eaten by animal type a

and the other constants are as previously defined. The concentration of tritium in animal feed is evaluated using Equations (9.28) and (9.29) with values defined for the animal feed crops.

The equation to calculate OBT in animal products assumes the specific activity in organic material equals the specific activity in the aqueous phase apart from a discrimination factor. This equation is adapted from the derivation of Peterson and Davis (2002).

$$C_{ap\_OBT} = C_{ap\_HTO} \; F_{dm\_ap} W_{eq\_ap} \; / \; F_{fw\_ap} \qquad (9.30b)$$

Default values for parameters in eqns (9.30a) and (9.30b), as recommended by Peterson and Davis (2002), are presented in Table 9.4. Values for fresh and dry matter fractions and for water equivalent factors are from Geigy (1981).

Elemental tritium (HT)

Releases of elemental tritium gas (HT) are a special case. Hydrogen in the elemental form is not readily taken up into vegetation. However, HT is slowly oxidized into tritiated water (HTO) by microbes in soil. Based on data from a release of HT at Chalk River that ran to equilibrium, Peterson and Davis (2002) found that an empirical relationship of 8 Bq L^{-1} /(Bq m^{-3}) for the ratio of HTO in air moisture to HT in air. This allows a simple addition to the model described above, in which most terms remain the same if C_{am} is approximated as 8 C_{caHT}. Peterson and Davis recommend that, for HT releases, the reduction factor for HTO, RF_{pp}, be replaced with a "supplement factor" numerically equal to 1.5.

Table 9.3 Parameter values for calculating HTO and OBT concentrations in plant products (adapted from Peterson and Davis 2002).

	Leafy vegetables	Fruit	Root and other vegetables	Grain	Pasture
Reduction factor (RF_{pp})	0.9	0.8	0.8	0.8	0.9
Reduction factor for leaves (RF_1)	0.9	0.9	0.9	0.9	0.9
Isotopic discrimination factor (ID_{pp})	0.9	0.9	0.9	0.9	0.9
Fresh matter fraction (F_{fw_pp})	0.906	0.853	0.824	0.117	0.8
Dry matter fraction (F_{dm_pp})	0.094	0.147	0.176	0.883	0.2
Water equivalent factor (W_{eq_pp})	0.6	0.59	0.58	0.577	0.616

Table 9.4. Parameter values for calculating HTO and OBT concentrations in animal products (adapted from Peterson and Davis 2002).

	Eggs	Milk	Beef	Pork	Poultry
Fresh weight fraction (F_{fw_ap})	0.74	0.897	0.668	0.50	0.67
Dry matter fraction (F_{dm_ap})	0.26	0.103	0.332	0.50	0.33
Water equivalent factor (W_{eq_ap})	0.835	0.669	0.795	0.904	0.796

9.6.2 Special Carbon-14 Models

The models for ^{14}C are similar to these for ^{3}H. The concentration of ^{14}C in vegetation from irrigation deposition is evaluated as follows.

$$C_{hcwC}(T_{yr}) = \frac{0.1\,F_{Cc}}{0.01\,P_3}\left[C_{sC}(T_{yr}) + \left(R_{wCt}\frac{1 - e^{-I_{sC}\,t_{gc}\,2.74E\text{-}3}}{I_{sC}} \right) \right] \qquad (9.31)$$

where $C_{hcwC}(T_{yr})$ = concentration of ^{14}C in crop type c at harvest from waterborne deposition for a year (Bq/kg wet weight)

$C_{sC}(T_{yr})$ = average surface soil concentration at soil location s for ^{14}C during the current year from material present at the start of the year (Bq/m^2)

R_{wCt} = constant deposition rate of ^{14}C from water for year t at water location w $(Bq/m^2/y)$

F_{Cc} = fraction of carbon in crop type c (kg carbon/kg plant)

P_3 = areal soil density of farmland soil (kg/m^2)

λ_{sC} = removal rate constant for activity of ^{14}C in the surface soil layer (y^{-1})

t_{gc} = growing period for crop c (d)

0.1 = assumed uptake of 10% of plant carbon from soil (dimensionless)

0.01 = average fraction of soil that is carbon (kg carbon/kg soil)

2.74E-3 = units conversion factor (y/d).

The deposition rate, R_{wCt}, is evaluated using Equation (9.5).

The concentration of ^{14}C in crops from atmospheric contamination is calculated as follows.

$$C_{hcaC}(T_{yr}) = \frac{C_{aaC}(T_{yr})\, F_{Cc}}{P_C} \tag{9.32}$$

where $C_{hcaC}(T_{yr})$ = concentration of ^{14}C in crop type c at harvest from atmospheric deposition at year t (Bq/kg wet weight)

$C_{aaC}(T_{yr})$ = annual average air concentration of carbon-14 at usage location a (Bq/m^3)

F_{Cc} = fraction of carbon in crop type c (dimensionless)

P_C = concentration of carbon in air (kg/m^3).

The concentration of ^{14}C in crops from contamination in the surface soil from initial or previous depositions is calculated from the annual average soil concentration, $C_{cC}(T_{yr})$.

$$C_{hcsC}(T_{yr}) = \frac{0.1\, F_{Cc}\, C_{sC}(T_{yr})}{0.01\, P_3} \tag{9.33}$$

where $C_{hcsC}(T_{yr})$ = concentration of ^{14}C in crop type c at harvest from soil root uptake for one year (Bq/kg wet weight)

F_{Cc} = fraction of carbon in crop type c (kg carbon/kg plant)

P_3 = areal soil density of farmland soil (kg/m^2)

0.1 = assumed uptake of 10% of plant carbon from soil (dimensionless)

0.01 = average fraction of soil that is carbon (kg carbon/kg soil)

The total concentration in food crops is evaluated as the sum of the contributions from the three routes (air, water, and soil), as follows.

$$C_{hcC}(T_{yr}) = C_{hcaC}(T_{yr}) + C_{hcwC}(T_{yr}) + C_{hcsC}(T_{yr}) \qquad (9.34)$$

where $C_{hcC}(T_{yr})$ = concentration of ^{14}C in crop type c at harvest for one year (Bq/kg wet weight).

and other terms are as previously defined. The concentration at harvest is the same as the concentration at the time of consumption by humans because of the long radiological half life of ^{14}C.

The concentration of ^{14}C in animal products is calculated as follows.

$$C_{caC}(t) = F_{Ca} \frac{\displaystyle\sum_{f=1}^{N_{fa}} C_{cfC} \ U_{af} \ d_{af}}{\displaystyle\sum_{f=1}^{N_{fa}} F_{Ca} \ U_{af}} \qquad (9.35)$$

where $C_{caC}(T_{yr})$ = concentration of ^{14}C in animal product a at time of consumption by humans (Bq/kg)

F_{Ca} = fraction of carbon in animal product a (dimensionless)

$C_{cfC}(T_{yr})$ = concentration of ^{14}C in animal feed type f at time of consumption for a year (Bq/kg wet weight)

U_{af} = daily feed intake rate for animal type a of feed type f (kg/d)

d_{af} = fraction of animal type a feed type f intake that is contaminated (dimensionless)

F_{Cf} = fraction of carbon in animal feed type f (dimensionless)

N_{fa} = number of feed crops eaten by animal type a.

This equation is simplified by noting that the carbon content in plants is much higher than in water.

10.0 INDIVIDUAL INTAKE MODULE

This section presents the models used to estimate intake of radionuclides by each ingestion and inhalation exposure pathway, and exposure to radionuclides from external exposure pathways. The models are the same for exposure of individuals and members of a population; the difference in the analysis is in the definition of parameter values. For an individual exposure analysis, the parameter values are generally selected to represent the reasonable maximum exposed (RME) individual. When a population analysis is performed, average values could be used to represent the average member of the population. The two types of calculations may also have parameters defined for specific individuals or groups of individuals. For example, exposure of workers may involve definition of a limited set of exposure routes, with exposure occurring only a fraction of the time (e.g, inhalation for 8 hours per day).

The estimation of intake from media concentrations involves multiplication of the medium concentration by an intake or exposure factor, an exposure duration, and other parameters as appropriate to each exposure pathway. This can be represented as the product of several terms, as indicated in Table 10.1.

Another consideration for the exposure models is age of the exposed individual. Each exposure route has parameters defined as a function of age. For example, water ingestion includes the rate of drinking water intake, usually expressed as liters per day. If the exposure assessment is being performed for a child, a different value would be assigned than for an analysis being performed for adults.

Table 10.1 General Intake Equation Terms

General Term	Description	Example Units
Medium concentration	radionuclide concentration in the exposure medium	Bq/L water Bq/m^3 air Bq/kg soil
Intake/contact rate	ingestion, inhalation, or exposure rate	L water/d m^3 air/d
Exposure duration	number of years over which the exposure is defined	Y
Daily activity factor	daily activity pattern parameter (e.g. exposure events per day, hours of exposure per day)	hr/d events/d · h/event
Annual activity factor	annual activity pattern parameter (e.g. days per year that exposure occurs)	days/year

The starting point parameter in the intake component analysis depends on the exposure pathway considered. For ingestion and inhalation pathways, the parameter is the medium average concentration. For external exposure pathways the parameter is the time-integrated media concentration. The parameters for each exposure pathway for acute and chronic releases are indicated in Table 10.2, along with the reference to the equation number describing their generation.

The exposure time, T, is represented as a general term in the equations. The time may be either the acute exposure period (e.g. T_{eg} for external ground exposure) or the chronic time period of one year (T_{yr}). For acute exposure situations, the exposure duration (as represented by the daily and annual exposure factor parameters) should not be greater than the exposure period defined for the analysis.

Table 10.2 Input Parameters for Intake Analyses

Exposure Route	Exposure Pathway	Acute Releases			Near-Field/Chronic Releases		
		Parameter	Units	Eq.	Parameter	Units	Eq.
External	Plume	$C_{eai}(T_{ex})$	Bq/m^3	5.1	$C_{eai}(T_{yr})$	Bq/m^3	7.12 5.1
	Ground	$C_{esi}(T_{eg})$	Bq/kg	8.6	$C_{esi}(T_{yr})$	Bq/kg	7.10

10.1 COMMUNICATION INTERFACES

The input files for the individual intake module are the global input data file (GID) and the exposure pathway media concentration output file (EPF). No auxiliary data communication files are needed. The exposure pathway media concentration output file (EPF) is generated by the near-filed, acute, or chronic exposure modules (or other external program that is capable of generating the proper file information). The GID file section for the individual intake module is generated by the user interface program. It contains information describing the scope of the analysis and all user-provided input parameters for an analysis. The structure and content of the files are given in Appendix A.

The output from the individual intake module is the annualized intake of contaminants from various media to which individuals or populations are exposed. For some pathways (those with dose rates associated rather than intakes), the dose rate information is passed instead, modified by the fraction of the time the individual was in the dose field. This information is provided in a primary data communication file, the receptor intake output file (RIF).

10.2 EXTERNAL EXPOSURE ESTIMATES

The time-average exposure parameter from the exposure component is used to determine the corresponding time-averaged exposure parameter for the intake component. The later parameter includes consideration of daily and annual individual activity patterns, and includes dependence on age of the exposed individual. This parameter and the total exposure time (1 year for chronic exposures and the time of plume passage for acute exposures) are carried forward to the Health Risk calculation in Section 11.

10.2.1 External Plume Immersion

The evaluation of the plume-immersion intake external-exposure parameter is performed as follows:

$$I_{eaig}(T) = C_{eai}(T)\, U_{eag}\, TC_p \tag{10.1}$$

where I_{eaig} = average exposure factor for external plume immersion exposure for radionuclide i for an individual in age group g (Bq/m^3)

C_{eai} = average air concentration at the location of the exposed individual for radionuclide i (Bq/m^3)

U_{eag} = daily exposure factor giving hours of plume immersion exposure per day for individuals in age group g (h/d)

$$\text{Tc}_p = \text{time correction set equal to } T_{eag}/(8760 \text{ h/y}) \text{ for chronic releases and the lesser of}$$
$$1.0 \text{ or } U_{eag} / T_{ex} * (8760 \text{ h/y}) \text{ for acute releases, where}$$

Tc_p = time correction set equal to $T_{eag}/(8760 \text{ h/y})$ for chronic releases and the lesser of 1.0 or $U_{eag} / T_{ex} * (8760 \text{ h/y})$ for acute releases, where

T_{eag} = annual exposure factor giving days of external plume immersion for individuals in age group g (d).

10.2.2 External Ground Exposure

The evaluation of the external ground exposure intake parameter is performed as follows.

$$I_{esig}(T) = C_{esi} U_{esg} \left[SH_h FT_{hg} + SH_o FT_{og} \right] T_{esg} \tag{10.2}$$

where $I_{esig}(T)$ = average exposure factor over time period T for external exposure to ground for radionuclide i for individuals in age group g (Bq/kg)

$C_{esi}(T)$ = average soil concentration at the location of individual exposure for radionuclide i for time period T (Bq/kg)

U_{esg} = daily exposure factor giving hours of exposure to contaminated ground per day for individuals in age group g (h/d)

SH_h = shield factor for exposure to soil while inside a home (dimensionless)

FT_{hg} = fraction of time spent inside a home for individuals in age group g (dimensionless)

SH_o = shield factor for exposure to soil while outside (dimensionless)

FT_{og} = fraction of time spent outside for individuals in age group g (dimensionless)

T_{esg} = annual exposure factor giving for external ground exposure for individuals in age group g (d). Generally set equal to 365 d for both chronic and acute exposures because continued exposure to soil following an acute deposition can be treated as a chronic exposure.

10.2.3 Recreational Swimming Immersion

The evaluation of the recreational swimming immersion intake parameter is performed as follows.

$$I_{wrig}(T) = C_{wri}(T) FE_{wrg} TE_{wrg} Tc_s \tag{10.3}$$

where $I_{wrig}(T)$ = average exposure factor over time period T for radionuclide i from swimming at recreational swimming location r for individuals in age group g (Bq/L)

$C_{wri}(T)$ = average water concentration over time period T for radionuclide i in surface water at the recreational swimming location r (Bq/L)

FE_{wrg} = frequency of swimming events at recreational swimming location r for individuals in age group g (events/d)

Tc_s = time correction set equal to $T_{wrg}/8760$ h/y for chronic releases and the lesser of 1.0 or $(FE_{wrg} * TE_{wrg} / T_{ew} * 8760)$ for acute releases

TE_{wrg} = duration of an average swimming event at recreational swimming location r for individuals in age group g (h/event)

T_{wrg} = annual exposure factor for swimming at recreational swimming location r for individuals in age group g (d).

For this pathway the daily exposure factor may be represented as the product of the event frequency, FE_{wrg}, and the event duration, TE_{wrg}.

10.2.4 Recreational Boating Exposure

The evaluation of the recreational boating exposure intake parameter is performed as follows.

$$I_{brig}(T) = C_{bri}(T) \, S B \, FE_{brg} \, TE_{brg} \, Tc_b \qquad (10.4)$$

where $I_{brig}(T)$ = average exposure factor over the period T for radionuclide i from boating at recreational boating location r for individuals in age group g (Bq/L)

C_{bri} = average water concentration of radionuclide i at recreational boating location r (Bq/L)

SB = shielding factor for boating exposures (dimensionless)

FE_{brg} = average frequency of daily boating events at recreational boating location r for individuals in age group g (events/d)

TE_{brg} = duration of an average boating event at recreational boating location r for individuals in age group g (h/event)

Tc_b = time correction set equal to $T_{brg}/8760$ h/y for chronic releases and the lesser of 1.0 or $(FE_{brg} * TE_{brg} / T_{eb} * 8760)$ for acute releases

$$T_{brg} = \text{annual exposure factor for boating at recreational boating location r for individuals in age group g (d).}$$

For this pathway the daily exposure factor may be represented as the product of the event frequency, FE_{brg}, and the event duration, TE_{brg}.

10.2.5 Recreational Shoreline Exposure

The evaluation of the recreational shoreline exposure intake parameter is performed as follows.

$$I_{srig}(T) = C_{sri}(T) \, SW_r \, FE_{srg} \, TE_{srg} \, T_{srg} \tag{10.5}$$

where $I_{srig}(T) =$ average exposure factor over the period T for radionuclide i from shoreline exposure at recreational shoreline location r for individuals in age group g (Bq/kg)

$C_{sri} =$ average shoreline sediment concentration of radionuclide i at recreational shoreline location r (Bq/kg)

$SW_r =$ shoreline width factor for the recreational shoreline location r (dimensionless)

$FE_{srg} =$ shoreline use event frequency at recreational shoreline location r for individuals in age group g (events/d)

TE_{srg} =   duration of each shoreline exposure event at recreational shoreline location r for individuals in age group g (h/event)

$T_{srg} =$ annual exposure factor for shoreline exposure at recreational shoreline location r for individuals in age group g (d). Generally set equal to 365 d for both chronic and acute exposures because continued exposure to soil following an acute deposition can be treated as a chronic exposure.

For this pathway the daily exposure factor may be represented as the product of the event frequency, FE_{srg}, and the event duration, TE_{srg}.

10.3 INGESTION INTAKE ESTIMATES

The input parameter for ingestion exposure pathways is the radionuclide concentration in the medium that contributes to the exposure. For example, the drinking water ingestion pathway uses the annual average water concentration at the point of consumption. The output parameter for ingestion pathways is the total intake of each radionuclide by an individual in each age group over the exposure period (acute or chronic). Evaluation of the intake amounts is described in the following sections for ingestion pathways.

10.3.1 Terrestrial Farm Product Ingestion

Terrestrial farm products include food crops and animal products. Food crops include leafy vegetables, other vegetables, cereal grains, and fruit. Animal products include cow's milk, beef/meat, poultry, and eggs (poultry).

The evaluation of the food crop intake parameter is performed as follows.

$$I_{csig} = C_{csi}(T) \, U_{csg} \, T_{csg} \, ED_{csg} \tag{10.6}$$

where $I_{csig}(T)$ = total intake radionuclide i in food crop c over the period T from ingestion at agricultural location s for individuals in age group g (Bq)

$C_{csi}(T)$ = average concentration in food crop c at agricultural location s for radionuclide i (Bq/kg)

U_{csg} = ingestion rate of food crop c at agricultural location s by an individual in age group g (kg/d)

T_{csg} = annual intake factor giving the days per year that food crop c is eaten at agricultural location s by individuals in age group g (d/y)

ED_{csg} = exposure duration for consumption of food crop c at agricultural location s for individuals in age group g (y).

The evaluation of the animal product intake parameter is performed as follows.

$$I_{asig} = C_{asi}(T) \, U_{asg} \, T_{asg} \, ED_{asg} \tag{10.7}$$

where $I_{asig}(T)$ = total intake radionuclide i in animal product a over the period T from ingestion at agricultural location s for individuals in age group g (Bq)

$C_{asi}(T)$ = average concentration in animal product a at agricultural location s for radionuclide i (Bq/kg)

U_{asg} = ingestion rate of animal product a at agricultural location s by an individual in age group g (kg/d)

T_{asg} = annual intake factor giving the days per year that animal product a is eaten at agricultural location s by individuals in age group g (d/y)

ED_{asg} = exposure duration for consumption of animal product a at agricultural location s for individuals in age group g (y).

10.3.2 Aquatic Food Ingestion

Four types of aquatic foods are considered: fish, mollusks, invertebrates, and water plants. The evaluation of the aquatic food intake parameter is performed as follows.

$$I_{fwig} = C_{fwi}(T) \, U_{fwg} \, T_{fwg} \, E \, D_{fwg} \qquad (10.8)$$

where $I_{fwig}(T)$ = total intake of radionuclide i from ingestion of aquatic food f over the period T at aquatic food location w for individuals in age group g (Bq)

$C_{fwi}(T)$ = average concentration in aquatic food f at aquatic food location w for radionuclide i (Bq/kg)

U_{fwg} = ingestion rate of aquatic food f at aquatic food location w by an individual in age group g (kg/d)

T_{fwg} = annual intake factor giving the days per year that aquatic food f is eaten at aquatic food location w by individuals in age group g (d/y)

ED_{fwg} = exposure duration for consumption of aquatic food f at aquatic food location w for individuals in age group g (y).

10.3.3 Drinking Water Ingestion

Evaluation of the drinking water intake parameter is performed as follows.

$$I_{dwig} = C_{dwi} \, U_{dw} \, T_{dwg} \, TC_w \qquad (10.9)$$

where $I_{dwig}(T)$ = total intake of radionuclide i from drinking water ingestion over the period T at water usage location w for individuals in age group g (Bq)

$C_{dwi}(T)$ = average concentration of radionuclide i in drinking water at water usage location w (Bq/L)

U_{dw} = drinking water ingestion rate (L/d)

T_{dwg} = annual intake factor giving days per year that water is consumed (d/yr)

TC_w = time correction equal to ED_{dwg} for chronic releases and T_{dw} for acute releases

ED_{dwg} = exposure duration for the drinking water pathway at usage location w for individuals in age group g (y)

10.3.4 Inadvertent Soil Ingestion

Evaluation of the inadvertent soil ingestion intake parameter is performed as follows.

$$I_{dsig}(T) = 10^{-6} C_{dsi}(T) \ U_{dsg} \ T_{dsg} \ ED_{dsg} \tag{10.10}$$

where $I_{dsig}(T)$ = total intake of radionuclide i from inadvertent soil ingestion over the period T at soil usage location s for individuals in age group g (Bq)

$C_{dsi}(T)$ = average soil concentration for radionuclide i at soil usage location s for time period T (Bq/m^2)

U_{dsg} = ingestion rate for soil at soil usage location s for individuals in age group g (mg/d)

T_{dsg} = annual intake factor giving days per year that soil ingestion occurs at soil usage location s for individuals in age group g (d/y)

ED_{ds} = exposure duration for the soil ingestion pathway at soil usage location s for individuals in age group g (y)

10^{-6} = units conversion factor (mg/kg)

10.3.5 Inadvertent Swimming Water Ingestion

The evaluation of the recreational swimming inadvertent intake parameter is performed as follows.

$$I_{wwig}(T) = C_{wri}(T) \ FE_{wrg} \ TE_{wrg} \ Tc_s \ U_{swg} \tag{10.11}$$

where $I_{wwig}(T)$ = average exposure factor over time period T for radionuclide i from ingestion at swimming location w for individuals in age group g (Bq)

$C_{wri}(T)$ = average water concentration over time period T for radionuclide i in surface water at the recreational swimming location r (Bq/L)

FE_{wrg} = frequency of swimming events at water use location r for individuals in age group g (events/d)

TE_{wrg} = duration of an average swimming event at water use location r for individuals in age group g (h/event)

Tc_s = time correction set equal to $T_{wrg}/8760$ h/y for chronic releases and the lesser of 1.0 or $(FE_{wrg} * TE_{wrg} / T_{ew} * 8760)$ for acute releases

T_{wrg} = annual exposure factor for swimming at water use location r for individuals in age group g (d)

U_{wwg} = uptake rate of water while swimming for age group g (L/hr).

For this pathway the daily exposure factor may be represented as the product of the event frequency, FE_{wrg}, and the event duration, TE_{wrg}.

10.3.6 Inadvertent Showering Water Ingestion

The evaluation of the showering inadvertent intake parameter is performed as follows.

$$I_{hwig}(T) = C_{dwi}(T) \, FE_{hrg} \, TE_{hrg} \, Tc_s \, U_{hwg} \qquad (10.12)$$

where $I_{hwig}(T)$ = average exposure factor over time period T for radionuclide i from showering ingestion at location r for individuals in age group g (Bq)

$C_{dwi}(T)$ = average concentration of radionuclide i in drinking water at water usage location w (Bq/L)

FE_{hrg} = frequency of showering events at water use location r for individuals in age group g (events/d)

TE_{hrg} = duration of an average shower event at water use location r for individuals in age group g (h/event)

Tc_s = time correction set equal to $T_{wrg}/8760$ h/y for chronic releases and the lesser of 1.0 or ($FE_{wrg} * TE_{wrg} / T_{ew} * 8760$) for acute releases

T_{hrg} = annual exposure factor for showering at water use location r for individuals in age group g (d)

U_{hwg} = uptake rate of water while showering for age group g (L/hr).

For this pathway the daily exposure factor may be represented as the product of the event frequency, FE_{hrg}, and the event duration, TE_{hrg}.

10.4 INHALATION INTAKE ESTIMATES

The input parameter for inhalation exposure pathways is the radionuclide concentration in the medium that contributes to the exposure. For example, the soil resuspension inhalation pathway uses the annual average air concentration above the area of contaminated soil. The output parameter for inhalation pathways is the total intake of each radionuclide by an individual

in each age group over the exposure period (acute or chronic). Evaluation of the intake amounts is described in the following sections for inhalation pathways.

10.4.1 Inhalation of Outdoor Air

Evaluation of the air inhalation intake parameter is performed as follows.

$$I_{aaig}(T) = C_{aai}(T)\, U_{aag}\, T_{aag}\, F_{aag}\, ED_{aag} \qquad (10.13)$$

where $I_{aaig}(T)$ = total intake of radionuclide i from air inhalation over the period T at air usage location a for individuals in age group g (Bq)

$C_{aai}(T)$ = average air concentration for radionuclide i at air usage location a over time period T (Bq/m^3)

U_{aag} = inhalation rate for air at air usage location a for individuals in age group g (m^3/d)

T_{aag} = annual intake factor giving days per year that air inhalation occurs at air usage location a for individuals in age group g (d/y)

F_{aag} = fraction of a day that outdoor inhalation occurs at location a for individuals in age group g (dimensionless)

ED_{aag} = exposure duration for the air inhalation pathway at air usage location a for individuals in age group g (y).

10.4.2 Inhalation of Resuspended Soil

Evaluation of the air inhalation intake parameter is performed as follows.

$$I_{saig}(T) = C_{sai}(T)\, U_{sag}\, F_{sag}\, T_{sag}\, ED_{sag} \qquad (10.14)$$

where $I_{saig}(T)$ = total intake of radionuclide i from resuspension inhalation over the period T at soil usage location a for individuals in age group g (Bq)

$C_{sai}(T)$ = average concentration of radionuclide i in soil over time period T at soil usage location s (Bq/m^2)

U_{sag} = inhalation rate of air for the resuspension pathway at soil usage location s for individuals in age group g (m^3/d)

F_{sag} = fraction of a day that resuspension inhalation exposure occurs at soil usage location s for individuals in age group g (dimensionless)

$T_{sag}=$ annual intake factor giving days per year that resuspension inhalation occurs at soil usage location s for individuals in age group g (d/y)

$ED_{sag} =$ exposure duration for the resuspension inhalation at soil usage location s for individuals in age group g (y)

10.4.3 Indoor Inhalation of Contaminants

Evaluation of the indoor air inhalation intake parameter for contaminants is performed as follows.

$$I_{vwig}(T) = [C_{aai}(t) + C_{vwi}(T)] U_{vwg} F_{vwg} T_{vwg} ED_{vwg} \tag{10.15}$$

where $I_{vwig}(T) =$ total intake of radionuclide i from indoor air inhalation over the period T at water usage location w for individuals in age group g (Bq)

$C_{aai}(T) =$ average outdoor air concentration for radionuclide i at air usage location a over time period T (Bq/m^3)

$C_{vwi}(T) =$ average indoor air concentration for volatile radionuclide i at water usage location w over time period T (Bq/m^3)

$U_{vwg} =$ inhalation rate for indoor air at water usage location w for individuals in age group g (m^3/d)

$F_{vwg} =$ fraction of a day that indoor inhalation occurs at water usage location w for individuals in age group g (dimensionless)

$T_{vwg} =$ annual intake factor giving days per year that indoor air inhalation occurs at water usage location w for individuals in age group g (d/y)

$ED_{vwg} =$ exposure duration for the indoor air inhalation pathway at water usage location w for individuals in age group g (y).

A special radon model is incorporated at this point. If the radionuclide in consideration is radon-222 (^{222}Rn), which has several short-lived progeny, the concentrations of the progeny may be set equal to some fraction of the radon activity. This is a radon equilibrium fraction model, designed to account for the partial buildup of radon progeny in indoor air. In essence, this model bypasses the chain decay processor calculation, and sets each of the progeny to a specific fraction of the parent activity. Thus, the parent radon concentration indoors is a function of the outdoor air and indoor volatilization, and the progeny are directly associated with that parent concentration.

11.0 DOSIMETRY AND HEALTH RISK MODULE

Estimates of radiation dose and health risk are performed based on the intake and external exposure parameters generated by the intake component. Radiation dose is expressed as either committed equivalent dose to a specific organ, or as the committed effective dose to an individual. The health risk is expressed as the incremental risk of cancer incidence or mortality. The methods for estimation of radiation dose and health risk are discussed in the following sections.

The input parameters for the dose and health risk evaluation are the intake parameters (for ingestion and inhalation) or the medium concentration average parameters and exposure times (for external exposure pathways) as generated by the intake component (defined in Section 10). Table 11.1 summarizes these parameters.

11.1 COMMUNICATION INTERFACES

The input files for the individual intake module are the global input data file (GID) and the receptor intake output file (RIF). Several auxiliary data communication files are needed if Federal Guidance Report 13 doses or risks are requested (index file, two ingestion dose and risk factor files, two inhalation dose and risk factor files, and external dose factor files for air, soil, and water). Other dosimetry data are taken from the FRAMES database via the GID file. The receptor intake output file (RIF) is generated by the individual intake module (or other external program that is capable of generating the proper file information). The GID file section for the impacts module is generated by the user interface program. It contains information describing the scope of the analysis and all user-provided input parameters for an analysis. The structure and content of the files are given in Appendices A and B.

The output from the impacts module is the annualized dose and risk from contaminants in various media to which individuals or populations are exposed. This information is provided in a primary data communication file, the health impacts output file (HIF).

11.2 RADIATION DOSE ASSESSMENT

The endpoints for radiation dose depend on the dose factors used as the basis of the analysis. Three sources of dose factors are in general use: 1) EPA supported values published in Federal Guidance Reports 11 and 12, 2) DOE supported values published in DOE reports, and 3) age dependent dose factors in reports of the International Commission on Radiological Protection (ICRP). All of these sources are based on recommendations of the ICRP. Each set of dose factors is described in the following sections.

Differences in parameter assumptions exist for some radionuclides between the EPA, DOE, and ICRP dosimetry, which have resulted in numerical differences between dose factors. The differences relate primarily to the biokinetic models for specific elements and to the weighting factors used to estimated the effective dose coefficients.

The dose parameter for specific organs is represented as the "committed equivalent dose" and is the sum of the average absorbed dose over all radiation types, as follows.

$$H_T(t) = \sum_R w_R D_{T,R}(t) \qquad (11.1)$$

where $H_T(\tau)$ = committed equivalent dose to target organ T over integrating period τ (Sv)

w_R = radiation weighting factor to derive the equivalent dose from the absorbed dose averaged over a tissue or organ and is based on the quality of radiation (dimensionless)

$D_{T,R}(\tau)$ = average absorbed dose to target organ T over integrating period τ from radiation of type R (Gy).

Both the absorbed dose and the equivalent dose have units of J kg^{-1}. Special units are defined for each term to indicate the application of the radiation weighting factor. The absorbed dose special unit is Gray (Gy) and the committed equivalent dose special unit is the Sievert (Sv).

Table 11.1 Input Parameters for Dosimetry and Health Risk Evaluation

Exposure Route	Exposure Pathway	Parameter	Units	Equation
External	Plume	$I_{eaig}(T)$	Bq/m^3	10.1
	Ground	$I_{esig}(T)$	Bq/kg	10.2
	Swimming	$I_{wrig}(T)$	Bq/L	10.3
	Boating	$I_{brig}(T)$	Bq/L	10.4
	Shoreline	$I_{srig}(T)$	Bq/kg	10.5
Ingestion	Farm Crops	$I_{csig}(T)$	Bq	10.6
	Animal Products	$I_{asig}(T)$	Bq	10.7
	Aquatic Foods	$I_{fwig}(T)$	Bq	10.8
	Drinking Water	$I_{dwig}(T)$	Bq	10.9
	Inadvertent Soil	$I_{dsig}(T)$	Bq	10.10
	Inadvertent Swim	$I_{wwig}(T)$	Bq	10.11
	Inadvertent Shower	$I_{hwig}(T)$	Bq	10.12
Inhalation	Air	$I_{aaig}(T)$	Bq	10.13
	Resuspended Soil	$I_{saig}(T)$	Bq	10.14
	Indoor Air	$I_{vwig}(T)$	Bq	10.15

The dose parameter representing the total effect to the body is the committed effective dose, $E(\tau)$. This parameter is estimated as the sum of the products of the committed organ or tissue equivalent doses and the appropriate organ or tissue weighting factors (w_T), over the integrating time, τ. The committed effective dose is calculated from the committed equivalent dose as follows.

$$E(t) = \sum_T w_T H_T(t) \qquad (11.2)$$

where $E(\tau)$ = committed effective dose over integrating period τ (Sv)

   w_T = tissue weighting factor, by which the equivalent dose in a tissue or organ is weighted to represent the relative contribution of that tissue or organ to the total detriment resulting from uniform irradiation of the body (dimensionless)

and $H_T(\tau)$ is calculated as per Equation (11.1). The units of the committed effective dose are the same as the units of the committed equivalent dose (Sv).

The time period of integration for worker dose coefficients is 50 years. The integration period for age-dependent dose coefficients is from the time of intake to 70 years. The age-dependent dose coefficients are provided for the age groups listed in Table 11.2.

A change in dose terminology occurred with release of ICRP Publication 60. Prior to this publication the effective dose, $E(\tau)$, was called the committed effective dose equivalent (CEDE). Also, the equivalent dose was previously called the dose equivalent. In the following discussions, the current terms are used: the CEDE is referred to as effective dose and the dose equivalent is referred to as the equivalent dose.

Table 11.2 Age-dependent Dose Coefficient Age Groups

Age at Intake	Age Range	Integrating Time, τ
3 mo	0 - 12 mo	69.75 y
1 y	1 - 2 y	69 y
5 y	>2 - 7 y	65 y
10 y	>7 - 12 y	60 y
15 y	>12 - 17 y	55 y
Adult	> 17 y	50 y

The dose coefficients are defined for several exposure routes and media and, in some cases, as a function of age. The nomenclature for representation of the dose coefficients is indicated in Table 11.3.

11.2.1 Federal Guidance Report Dosimetry

The EPA dose coefficients are provided in Federal Guidance Reports (FGR) 11 and 12 (EPA 1988 and EPA 1993). Coefficient values of organ-specific equivalent dose and effective dose are provided for inhalation and ingestion in FGR 11, and for external exposure to air, water, and soil in FGR 12. The internal dose coefficient values are based primarily on recommendations in ICRP Publications 26 and 30, and are to be used for evaluation of dose to adults (workers). The integration period for internal dose conversion factors is 50 years. The external dose conversion factors are also based on ICRP Publication 30 tissue weighting factors. These are included in the GENII-V2 libraries under the general heading of "ICRP-30/48."

11.2.2 Department of Energy Dosimetry

The DOE (1988a and 1988b) values are for workers and are based on ICRP Publications 26 and 30. They provide estimates of equivalent dose for specific organs in addition to the effective dose. There are some differences in the numerical evaluation of dose coefficients between the DOE publication and the EPA FGR publications and differences in numerical values can be found. Dose coefficients are provide for inhalation and ingestion intakes in DOE (1988b) and for external exposure to air, ground, and water in DOE (1988a). These are similar enough to the EPA guidance that the ICRP-30/48 values are used for both.

11.2.3 ICRP Dosimetry

The ICRP has published dose coefficients for estimation of dose to workers and to members of the public. Worker committed effective dose factors are based on a 50 year work period with the target individual being an adult. Worker dose coefficients are given in ICRP Publications 68. The ICRP age dependent committed equivalent dose coefficients are for estimation of dose to the public. Age-dependent committed equivalent dose and committed effective dose coefficient values for ingestion are given in ICRP Publications 56, 67, and 69, and values for inhalation are given in ICRP Publication 71. ICRP Publication 72 presents committed effective dose coefficients as a function of age for ingestion and inhalation (organ specific committed equivalent dose coefficients are not presented in this publication). Table 11.4 summarizes the content of each of these reports. These values form the underlying basis for Federal Guidance Report 13; they are included in the GENII-V2 libraries under the general heading of "ICRP-60."

Table 11.3 Dose and Risk Coefficient Nomenclature

Dose Coefficient	General Symbol	Subscript Description	
		Position	Uses
Effective Dose	EC_{123}	1	radionuclide - i
		2	age group g - general a - adult
		3	exposure route/medium a - external, <u>a</u>ir g - external, <u>g</u>round o - ingestion, <u>o</u>ral r - inhalation, <u>r</u>espiration w - external, <u>w</u>ater
		4	inhalation or ingestion class – c inhalation (F,M,S) ingestion (f1)
Equivalent Dose	HC_{1234}	1,2,3,4	same as above
		5	organ - T

11.2.4 <u>External Exposure Pathway Dose Assessment</u>

Radiation dose from external exposure pathways is evaluated using the average medium concentrations, the exposure times, and the external dose coefficient appropriate to the medium. The external dose coefficients are provided for exposure of adults in FGR 12 (EPA 1993) in terms of equivalent dose to specific organs and the effective dose for an individual. The dose coefficients are presented as dose rate factors that are multiplied by the medium average concentration and exposure time to give the total radiation dose for the defined exposure period. The following equations describe estimation of the equivalent dose and effective dose from external exposure pathways.

External Exposure from Air Immersion The evaluation of radiation dose from a plume of radioactivity may be evaluated using the finite plume model or the semi-infinite plume model. When the finite plume model is used the dose is evaluated by the atmospheric transport component (Section 5.4) because the dose is a function of plume dimensions. When the semi-infinite plume model is used, the atmospheric transport analysis provides the time-integral of

Table 11.4 Summary of ICRP Publication Dose Coefficients

Publication No. Target Group	Dose Type	Intake Route	Lung Model	Elements	Basis for w_T
56 (1989) Public, Part 1	$E(\tau)$ $H_T(\tau)$	Ingestion	NA	H, C, Sr, Zr, Nb, Ru, I, Cs, Ce, Pu, Am, Np	ICRP 26
67 (1993) Public, Part 2	$E(\tau)$ $H_T(\tau)$	Ingestion	NA	S, Co, Ni, Zn, Sr, Mo, Tc, Ag, Te, Ba, Pb, Po, Ra	ICRP 60

185

$$IE_{eaig}(T) = I_{eaig}(T) \ EC_{iaa} \ TE_a \ 3.15 \times 10^7 \tag{11.4}$$

where $IE_{eaig}(T)$ = effective dose from external exposure to radionuc lide i from plume immersion at air usage location a for an individual in age group g (Sv)

$I_{eaig}(T)$ = external exposure average air concentration for radionuclide i for plume immersion at air usage location a for individuals in age group g (Bq/m^3)

EC_{iaa} = effective dose coefficient for external exposure from plume immersion for radionuclide i for an adult (Sv m^3 per Bq s).

TE_a = time of exposure, either T_{ex} for acute releases or T_{yr} for chronic releases (y)

3.15×10^7 = units correction (s/y).

As indicated in these equations, the adult equivalent dose (HC_{iaaT}) and effective dose coefficients (EC_{iaa}) are used for all age groups, as represented by the subscript "a" (adult) in place of the general age group subscript "g". This is a necessary approximation because age-dependent effective dose coefficients are not available for external exposures.

External Exposure from Ground Contamination The equivalent dose from external exposure to contaminated ground is evaluated as follows.

$$IH_{esigT}(T) = I_{esig}(T) \ HC_{iagT} \ TE_g \ 3.15 \times 10^7 / \rho_s \ d_s \tag{11.5}$$

where $IH_{esigT}(T)$ = equivalent dose to organ T from external exposure to radionuclide i from plume immersion at soil usage location s for an individual in age group g for exposure over time period T (Sv)

$I_{esig}(T)$ = external exposure average soil concentration for radionuclide i for plume immersion at soil usage location s for individuals in age group g for exposure over time period T (Bq/kg)

HC_{iagT} = equivalent dose coefficient to organ T for external exposure to ground for radionuclide i for an adult (Sv m^2 per Bq s)

TE_g = time of exposure, either T_{eg} for acute releases or T_{yr} for chronic releases (y)

ρ_s = surface soil bulk density (kg/m^3)

d_s = thickness of surface soil layer (m)

3.15×10^7 = units correction (s/y).

The effective dose from external exposure to contaminated ground is evaluated as follows.

$$IE_{esig}(T) = I_{esig}(T) \ EC_{iag} \ TE_g \ 3.15 \times 10^7 \ / \ \rho_s \ d_s \qquad (11.6)$$

where 　$IE_{esig}(T)$ = effective dose from external exposure to radionuclide i in contaminated soil at soil usage location s for an individual in age group g for exposure over time period T (Sv)

　　　$I_{esig}(T)$ = external exposure average of soil concentration for radionuclide i for soil at soil usage location s for individuals in age group g for exposure over time period T (Bq/kg)

　　　EC_{iag} = effective dose equivalent factor for external exposure from ground exposure (g) for radionuclide i for an adult (Sv m^2 per Bq s)

　　　TE_g = time of exposure, either T_{eg} for acute releases or T_{yr} for chronic releases (y)

　　　ρ_s = surface soil bulk density (kg/m^3)

　　　d_s = thickness of surface soil layer (m)

　　3.15×10^7 = units correction (s/y).

External Exposure from Swimming　The equivalent dose from external exposure while swimming is evaluated as follows.

$$IH_{wrigT}(T) = 10^{-3} \ I_{wrig}(T) \ HC_{iawT} \ TE_w \ 3.15 \times 10^7 \qquad (11.7)$$

where 　$IH_{wrigT}(T)$ = equivalent dose to organ T from external exposure to radionuclide i while swimming at recreational water usage location r for an individual in age group g for exposure over time period T (Sv)

　　　$I_{wrig}(T)$ = external exposure average water concentration for radionuclide i for swimming at recreational water usage location r for individuals in age group g for exposure over time period T (Bq/m^3)

　　　HC_{iagT} = equivalent dose coefficient to organ T for external exposure from water immersion for radionuclide i for an adult (Sv L per Bq s)

　　　10^{-3} = unit conversion factor (m^3/L)

　　　TE_w = time of exposure, either T_{ew} for acute releases or T_{yr} for chronic releases (y)

3.15×10^7 = units correction (s/y).

The effective dose from external exposure to swimming in contaminated water is evaluated as follows.

$$IE_{wrig}(T) = 10^{-3} I_{wrig}(T) \, EC_{iaw} \, TE_w \, 3.15 \times 10^7 \qquad (11.8)$$

where $IE_{wrig}(T)$ = effective dose from external exposure to radionuclide i in contaminated water at recreational water usage location r for an individual in age group g (Sv)

$I_{wrig}(T)$ = external exposure average water concentration for radionuclide i for recreational water usage location r for individuals in age group g (Bq/m^3)

E_{iaw} = effective dose equivalent factor for external exposure from water immersion (w) for radionuclide i for an adult (Sv L per Bq s)

10^{-3} = unit conversion factor (m^3/L)

TE_w = time of exposure, either T_{ew} for acute releases or T_{yr} for chronic releases (y)

3.15×10^7 = units correction (s/y).

External Exposure from Boating The equivalent dose from external exposure while boating is evaluated as follows.

$$IH_{brigT}(T) = 10^{-3} I_{brig}(T) \, HC_{iawT} \, TE_b \, 3.15 \times 10^7 / 2 \qquad (11.9)$$

where $IH_{brigT}(T)$ = equivalent dose to organ T from external exposure to radionuclide i while boating at recreational water usage location r for an individual in age group g for exposure over time period T (Sv)

$I_{brig}(T)$ = external exposure average water concentration for radionuclide i while boating at recreational water usage location r for individuals in age group g for exposure over time period T (Bq /L)

HC_{iawT} = equivalent dose coefficient to organ T for external exposure from water immersion (w) for radionuclide i for an adult (Sv m^3 per Bq s)

10^{-3} = unit conversion factor (m^3/L)

TE_b = time of exposure, either T_{eb} for acute releases or T_{yr} for chronic releases (y)

2 = factor to account for being at the water surface rather than immersed (dimensionless)

3.15×10^7 = units correction (s/y).

The effective dose from external exposure to boating in contaminated water is evaluated as follows.

$$IE_{brig}(T) = I_{brig}(T)\ EC_{iaw}\ TE_b\ 3.15 \times 10^7\ /\ 2 \qquad (11.10)$$

where $IE_{brig}(T)$ = effective dose from external exposure to radionuclide i from boating in contaminated water at recreational water usage location r for an individual in age group g (Sv)

  $I_{brig}(T)$ = external exposure average water concentration for radionuclide i for recreational water usage location r for individuals in age group g (Bq/L)

  E_{iaw} = effective dose equivalent factor for external exposure from water immersion (w) for radionuclide i for an adult (Sv m^3 per Bq s)

  10^{-3} = unit conversion factor (m^3/L)

  TE_b = time of exposure, either T_{eb} for acute releases or T_{yr} for chronic releases (y)

  2 = factor to account for being at the water surface rather than immersed (dimensionless)

  3.15×10^7 = units correction (s/y).

External Exposure from Shoreline Sediment The equivalent dose from external exposure to contaminated shoreline is evaluated as follows.

$$IH_{srigT}(T) = I_{srig}(T)\ HC_{iagT}\ TE_s\ 3.15 \times 10^7\ /\ \rho_s\ d_s \qquad (11.11)$$

where $IH_{srigT}(T)$ = equivalent dose to organ T from external exposure to radionuclide i from shoreline sediment at recreational water usage location r for an individual in age group g for exposure over time period T (Sv)

  $I_{srig}(T)$ = external exposure average sediment concentration for radionuclide i for shoreline sediment at recreational water usage location r for individuals in age group g for exposure over time period T (Bq/kg)

  HC_{iagT} = equivalent dose coefficient to organ T for external exposure to ground for radionuclide i for an adult (Sv m^3 per Bq s)

TE_s = time of exposure, either T_{es} for acute releases or T_{yr} for chronic releases (y)

ρ_s = surface soil bulk density (kg/m^3)

d_s = thickness of surface soil layer (m)

3.15×10^7 = units correction (s/y).

The effective dose from external exposure to shoreline sediment is evaluated as follows.

$$IE_{srig}(T) = I_{srig}(T)\, EC_{iag}\, TE_s\, 3.15 \times 10^7 / \rho_s\, d_s \tag{11.12}$$

where $IE_{srig}(T)$ = effective dose from external exposure to radionuclide i in shoreline sediment at recreational water usage location r for an individual in age group g (Sv)

$I_{srig}(T)$ = external exposure average shoreline sediment concentration for radionuclide i for recreational water usage location r for individuals in age group g (Bq/m^2)

EC_{iag} = effective dose equivalent factor for external exposure from contaminated soil (g) for radionuclide i for an adult (Sv m^2 per Bq s)

TE_s = time of exposure, either T_{es} for acute releases or T_{yr} for chronic releases (y)

ρ_s = surface soil bulk density (kg/m^3)

d_s = thickness of surface soil layer (m)

3.15×10^7 = units correction (s/y).

The soil external effective dose equivalent factor is used for the shoreline sediment exposure pathway. A shore width factor is applied in evaluation of the time-integral of shoreline sediment concentration to account for the narrow width of the shoreline (less than infinite), as described in Section 10.

11.2.5 Ingestion Exposure Pathway Dose Assessment

The equivalent dose and effective dose are evaluated for each ingestion exposure pathway using the ingestion dose coefficients as defined in Sections 11.1.1 through 11.1.3. The evaluation is similar for all ingestion pathways; the medium concentration intake parameter (e.g. $I_{csig}(T)$) is multiplied by the appropriate dose coefficient (i.e., HC_{12oc5} or EC_{12oc} as defined in Table 11.3). The following equations describe calculation of radiation doses for food crops, animal products, aquatic foods, drinking water, and soil ingestion pathways.

Ingestion of Food Crops The equivalent dose from ingestion of food crops (leafy vegetables, other vegetables, fruit, and cereal grains) is evaluated as follows.

$$IH \quad (T) = I \quad (T) \, HC$$

where $IH_{csigT}(T)$ = equivalent dose to organ T from ingestion intake of radionuclide i in food crop c at soil usage location s for an individual in age group g for exposure over time period T (Sv)

   $I_{csig}(T)$ = ingestion intake of radionuclide i in food crop c at soil location s for individuals in age group g for exposure over time period T (Bq)

   HC_{igocT} = equivalent dose coefficient to organ T for ingestion intake of radionuclide I of class c for an individual in age group g (Sv/Bq).

   The effective dose from ingestion of food crops is evaluated as follows.

where $IE_{csig}(T)$ = effective dose from ingestion intake of radionuclide i in food crop c at soil usage location s for an individual in age group g for exposure over time period T (Sv)

   $I_{csig}(T)$ = ingestion intake of radionuclide i in food crop c at soil location s for individuals in age group g for exposure over time period T (Bq)

   EC_{igoc} = effective dose coefficient for ingestion intake of radionuclide I of class c for an individual in age group g (Sv/Bq).

Ingestion of Animal Products The equivalent dose from ingestion of animal products (beef/meat, cow's milk, poultry, and eggs) is evaluated as follows.

where $IH_{asigT}(T)$ = equivalent dose to organ T from ingestion intake of radionuclide i in animal product a at soil usage location s for an individual in age group g for exposure over time period T (Sv)

   $I_{asig}(T)$ = ingestion intake of radionuclide i in animal product a at soil location s for individuals in age group g for exposure over time period T (Bq)

   HC_{igocT} = equivalent dose coefficient to organ T for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

191

The effective dose from ingestion of animal products is evaluated as follows.

$$IE_{asig}(T) = I_{asig}(T) \; EC_{igoc} \qquad (11.16)$$

where $IE_{asig}(T)$ = effective dose from ingestion intake of radionuclide i in animal product a at soil usage location s for an individual in age group g for exposure over time period T (Sv)

$I_{asig}(T)$ = ingestion intake of radionuclide i in animal product a at soil location s for individuals in age group g for exposure over time period T (Bq)

EC_{igoc} = effective dose coefficient for ingestion intake of radionuclide i for an individual in age group g (Sv/Bq).

Ingestion of Aquatic Foods The equivalent dose from ingestion of aquatic foods (fish, crustaceans, mollusks, and aquatic plants) is evaluated as follows.

$$IH_{fwigT}(T) = I_{fwig}(T) \; HC_{igocT} \qquad (11.17)$$

where $IH_{fwigT}(T)$ = equivalent dose to organ T from ingestion intake of radionuclide i in aquatic food f at water usage location w for an individual in age group g for exposure over time period T (Sv)

$I_{fwig}(T)$ = ingestion intake of radionuclide i in aquatic food f at water usage location w for individuals in age group g for exposure over time period T (Bq)

HC_{igocT} = equivalent dose coefficient to organ T for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

The effective dose from ingestion of aquatic foods is evaluated as follows.

$$IE_{fwig}(T) = I_{fwig}(T) \; EC_{igoc} \qquad (11.18)$$

where $IE_{fwig}(T)$ = effective dose from ingestion intake of radionuclide i in aquatic food f at water usage location w for an individual in age group g for exposure over time period T (Sv)

$I_{fwig}(T)$ = ingestion intake of radionuclide i in aquatic food f at water usage location w for individuals in age group g for exposure over time period T (Bq)

EC_{igoc} = effective dose coefficient for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

Ingestion of Drinking Water The equivalent dose from ingestion of drinking water is evaluated as follows.

$$IH_{dwigT}(T) = I_{dwig}(T) \ HC_{igocT} \qquad (11.19)$$

where $IH_{dwigT}(T)$ = equivalent dose to organ T from ingestion intake of radionuclide i in drinking water at water usage location w for an individual in age group g for exposure over time period T (Sv)

$I_{dwig}(T)$ = ingestion intake of radionuclide i in drinking water at water usage location w for individuals in age group g for exposure over time period T (Bq)

HC_{igocT} = equivalent dose coefficient to organ T for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

The effective dose from ingestion of drinking water is evaluated as follows.

$$IE_{dwig}(T) = I_{dwig}(T) \ EC_{igoc} \qquad (11.20)$$

where $IE_{dwig}(T)$ = effective dose from ingestion intake of radionuclide i in drinking water at water usage location w for an individual in age group g for exposure over time period T (Sv)

$I_{dwig}(T)$ = ingestion intake of radionuclide i in drinking water at water usage location w for individuals in age group g for exposure over time period T (Bq)

EC_{igoc} = effective dose coefficient for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

Ingestion of Soil The equivalent dose from inadvertent ingestion of soil is evaluated as follows.

$$IH_{dsigT}(T) = I_{dsig}(T) \ HC_{igocT} \qquad (11.21)$$

where $IH_{dsigT}(T)$ = equivalent dose to organ T from ingestion intake of radionuclide i in soil at soil usage location s for an individual in age group g for exposure over time period T (Sv)

$I_{dsig}(T)$ = ingestion intake of radionuclide i in soil at soil location s for individuals in age group g for exposure over time period T (Bq)

HC_{igocT} = equivalent dose coefficient to organ T for ingestion intake of radionuclide I of class c for an individual in age group g (Sv/Bq).

The effective dose from inadvertent ingestion of soil is evaluated as follows.

$$IE_{dsig}(T) = I_{dsig}(T) \ EC_{igo\,c} \qquad (11.22)$$

where $IE_{dsig}(T)$ =   effective dose from ingestion intake of radionuclide i in soil at soil usage location s for an individual in age group g for exposure over time period T (Sv)

     $I_{dsig}(T)$ = ingestion intake of radionuclide i in soil at soil location s for individuals in age group g for exposure over time period T (Bq)

     EC_{igoc} = effective dose coefficient for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

Ingestion of Water While Swimming The equivalent dose from inadvertent ingestion of water while swimming is evaluated as follows.

$$IH_{w\mathrm{wig}T}(T) = I_{w\,\mathrm{wig}}(T) \ HC_{igo\,c\,T} \qquad (11.23)$$

where $IH_{wwigT}(T)$ = equivalent dose to organ T from ingestion intake of radionuclide i in water at water usage location w for an individual in age group g for exposure over time period T (Sv)

     $I_{wwig}(T)$ = ingestion intake of radionuclide i while swimming at water usage location w for individuals in age group g for exposure over time period T (Bq)

     HC_{igocT} = equivalent dose coefficient to organ T for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

The effective dose from inadvertent ingestion of water while swimming is evaluated as follows.

$$IE_{w\,\mathrm{wig}}(T) = I_{w\,\mathrm{wig}}(T) \ EC_{igo\,c} \qquad (11.24)$$

where $IE_{wwig}(T)$ = effective dose from ingestion intake of radionuclide i in swimming water at water usage location w for an individual in age group g for exposure over time period T (Sv)

     $I_{wwig}(T)$ = ingestion intake of radionuclide i in swimming water at water usage location w for individuals in age group g for exposure over time period T (Bq)

     EC_{igoc} = effective dose coefficient for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

Ingestion of Water While Showering The equivalent dose from inadvertent ingestion of water while showering is evaluated as follows.

$$IH_{hwigT}(T) = I_{hwig}(T)\, HC_{igocT} \tag{11.25}$$

where $IH_{hwigT}(T)$ = equivalent dose to organ T from ingestion intake of radionuclide i in shower water at water usage location w for an individual in age group g for exposure over time period T (Sv)

$I_{hwig}(T)$ = ingestion intake of radionuclide i in shower water at water usage location w for individuals in age group g for exposure over time period T (Bq)

HC_{igocT} = equivalent dose coefficient to organ T for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

The effective dose from inadvertent ingestion of shower water is evaluated as follows.

$$IE_{hwig}(T) = I_{hwig}(T)\, EC_{igoc} \tag{11.26}$$

where $IE_{hwig}(T)$ = effective dose from ingestion intake of radionuclide i in shower water at water usage location w for an individual in age group g for exposure over time period T (Sv)

$I_{hwig}(T)$ = ingestion intake of radionuclide i in shower water at water usage location w for individuals in age group g for exposure over time period T (Bq)

EC_{igoc} = effective dose coefficient for ingestion intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

11.2.6 Inhalation Exposure Pathway Dose Assessment

The equivalent dose and effective dose are evaluated for each inhalation exposure pathway using the inhalation dose coefficients as defined in Sections 11.1.1 through 11.1.3. The evaluation is similar for all inhalation pathways; the medium concentration intake parameter (e.g. $I_{csig}(T)$) is multiplied by the appropriate dose coefficient (i.e., HC_{12rc5} or EC_{12rc} as defined in Table 11.3). The following equations describe calculation of radiation doses for inhalation of air, resuspended soil, and indoor air contaminants.

Inhalation of Air The equivalent dose from inhalation of air is evaluated as follows.

$$IH_{aaigT}(T) = I_{aaig}(T)\, HC_{igrcT} \tag{11.27}$$

where $IH_{aaigT}(T)$ = equivalent dose to organ T from inhalation intake of radionuclide i in air at air usage location a for an individual in age group g for exposure over time period T (Sv)

$I_{aaig}(T) =$ inhalation intake of radionuclide i in air at air usage location a for individuals in age group g for exposure over time period T (Bq)

$HC_{igrcT} =$ equivalent dose coefficient to organ T for inhalation intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

The effective dose from inhalation of air is evaluated as follows.

$$IE_{aaig}(T) = I_{aaig}(T) \ EC_{igrc} \qquad (11.28)$$

where $IE_{aaig}(T) =$ effective dose from inhalation intake of radionuclide i in air at air usage location a for an individual in age group g for exposure over time period T (Sv)

$I_{aaig}(T) =$ inhalation intake of radionuclide i in air at air usage location a for individuals in age group g for exposure over time period T (Bq)

$EC_{igrc} =$ effective dose coefficient for inhalation intake of radionuclide i oc class c for an individual in age group g (Sv/Bq).

Inhalation of Resuspended Soil The equivalent dose from inhalation of resuspended soil is evaluated as follows.

$$IH_{saigT}(T) = I_{saig}(T) \ HC_{igrcT} \qquad (11.29)$$

where $IH_{saigT}(T) =$ equivalent dose to organ T from inhalation intake of radionuclide i in resuspended soil at air usage location a for an individual in age group g for exposure over time period T (Sv)

$I_{saig}(T) =$ inhalation intake of radionuclide i in resuspended soil at air usage location a for individuals in age group g for exposure over time period T (Bq)

$HC_{igrcT} =$ equivalent dose coefficient to organ T for inhalation intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

The effective dose from inhalation of resuspended soil is evaluated as follows.

$$IE_{saig}(T) = I_{saig}(T) \ EC_{igrc} \qquad (11.30)$$

where $IE_{saig}(T) =$ effective dose from inhalation intake of radionuclide i in resuspended soil at air usage location a for an individual in age group g for exposure over time period T (Sv)

196

$I_{saig}(T)$ = inhalation intake of radionuclide i in resuspended soil at air usage location a for individuals in age group g for exposure over time period T (Bq)

EC_{igrc} = effective dose coefficient for inhalation intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

Inhalation of Indoor Air The equivalent dose from inhalation of contaminants in indoor air is evaluated as follows.

$$IH_{vwigT}(T) = I_{vwig}(T) \, HC_{igrcT} \tag{11.31}$$

where $IH_{vwigT}(T)$ = equivalent dose to organ T from inhalation intake of radionuclide i in indoor air at location w for an individual in age group g for exposure over time period T (Sv)

$I_{vwig}(T)$ = inhalation intake of radionuclide i in indoor air at location w for individuals in age group g for exposure over time period T (Bq)

HC_{igrcT} = equivalent dose coefficient to organ T for inhalation intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

The effective dose from inhalation in indoor air is evaluated as follows.

$$IE_{vwig}(T) = I_{vwig}(T) \, EC_{igrc} \tag{11.32}$$

where $IE_{vwig}(T)$ = effective dose from inhalation intake of radionuclide i in indoor air at location w for an individual in age group g for exposure over time period T (Sv)

$I_{vwig}(T)$ = inhalation intake of radionuclide i in indoor air at location w for individuals in age group g for exposure over time period T (Bq)

EC_{igrc} = effective dose coefficient for inhalation intake of radionuclide i of class c for an individual in age group g (Sv/Bq).

11.3 HEALTH RISK ASSESSMENT

Three primary methods are available to perform the assessment of health impacts: 1) use of effective dose estimates multiplied by health effects conversion factors, 2) use of intake estimates multiplied by cancer incidence slope factor published in EPA Health Effects Assessment Summary Tables, 3) calculation using organ-dependent health effect conversion factors. Each of these methods is discussed in the following sections.

11.3.1 Use of Effective Dose

An estimate of the health impacts, expressed as risk of a defined health effect, can be made from the effective dose and appropriate health effect conversion factors. The health effect conversion factors must be defined for each age group or for adults and must be representative of the exposed population (i.e., workers or the public). General health effect conversion factors are presented in ICRP Publication 60 (1990) for exposure of workers and the whole population for health effects expressed as fatal cancer, non-fatal cancer, and severe hereditary effects.

Estimation of the health impacts is performed as follows for exposure pathway 1, medium 2, radionuclide i, age group g, and health effect h.

$$IR_{12igh}(T) = IE_{12ig}(T)\, HC_{gh} \qquad (11.33)$$

where $IR_{12igh}(T)$ = health effects h risk, for age group g, radionuclide i, exposure pathway 1, medium 2, (lifetime risk from exposure during period T)

$IE_{12ig}(T)$ = effective dose from exposure to pathway 1, usage location 2, for radionuclide i and an individual in age group g over exposure time period T (Sv)

HC_{gh} = health effects conversion factor for effect h and an individual in age group g (risk/Sv)

The subscripts 1 and 2 are as defined in Table 11.1 for the intake parameter, $I_{12ig}(T)$.

Use of the ICRP Publication 60 health effects conversion factors could be represented in Equation (11.33) by replacing the age group subscript "g" with and "a" to represent adults, as suggested in Table 11.3.

The health impact parameter, $IR_{12igh}(T)$, can be summed in various ways to estimate the total impact as a function of pathway, location, or age group. For example, the total health risk to an individual from food crop ingestion is given as follows, with summations over food crop types and radionuclides, at location s.

$$IR_{CsIgh}(T) = \sum_{c=1}^{N_c} \sum_{i=1}^{N_i} IR_{csigh}(T) \qquad (11.34)$$

where $IR_{CsIgh}(T)$ = health effects h risk, for an individual in age group g, over exposure time period T, at soil usage location s, summed over all farm crop types and radionuclides (risk)

N_c = number of farm crop types consumed by the individual at the usage location (dimensionless)

N_i = number of radionuclides considered at usage location s (dimensionless)

and other terms are as previously defined. In this equation, summations are indicated by a capitalized subscript, e.g., the C (farm crop) and I (radionuclide) are capitalized in the risk parameter, $IR_{CsIg}(T)$, indicating the value is the sum over farm crop types and radionuclides.

11.3.2 Use of HEAST Slope Factors

The EPA has developed slope factors (Eckerman et al. 2000) for exposure to radionuclides via inhalation, ingestion, and external direct radiation from contamination on a ground plane. This method may be used only to estimate lifetime cancer incidence because the slope factors are specific to total cancer incidence in the general population. The slope factors for ingestion and inhalation are expressed in units of risk per pCi intake, and the external slope factors are expressed as a rate in units of risk/y per pCi/g soil. The following equations indicate use of these factors, with unit conversions, for estimation of total cancer incidence from exposure of the population. This approach is essentially equivalent to the FGR 13 approach (Section 11.3.3)

The ingestion slope factors are to be applied to the ingestion intake estimates for an adult, as follows.

$$IR_{12iah}(T) = 27 \ I_{12ia}(T) \ SF_{io} \qquad (11.35)$$

where $IR_{12iah}(T)$ = lifetime cancer incidence risk (effect h) from ingestion exposure via pathway 1, medium 2, radionuclide i, for the general population (a), for exposure over the period T (risk)

$I_{12ia}(T)$ = ingestion intake of radionuclide i via exposure pathway 1, at usage location 2, for the adult age group (a) over exposure time period T (Bq)

SF_{io} = slope factor for ingestion (o) of radionuclide i (risk/Bq)

27 = units conversion factor (pCi/Bq).

The exposure and location pathways include all those involving ingestion intake (i.e., subscript pairs cs, as, fw, dw, and ds as per Table 11.1).

The inhalation slope factors are applied in a similar manner to the inhalation intake estimates for an adult, as follows.

$$IR_{eliah}(T) = 27 \ I_{elia}(T) \ SF_{io} \qquad (11.36)$$

where $IR_{eliah}(T)$ = lifetime cancer incidence risk (effect h) from inhalation exposure via pathway e, medium l, radionuclide i for the general population (a), for exposure over the period T (risk)

$I_{elia}(T)$ = inhalation intake of radionuclide i via exposure pathway e, for medium l, for the adult age group (a) over exposure time period T (Bq)

SF_{ir} = slope factor for inhalation (r) of radionuclide i (risk/pCi)

27 = units conversion factor (pCi/Bq).

The exposure and location pathways include all those involving inhalation intake (i.e., subscript pairs aa, sa, and vw as per Table 11.1).

The EPA external slope factors for ground exposure can be applied to the ground external exposure pathway and the shoreline sediment external exposure pathway. For the ground exposure pathway the risk is evaluated as follows.

$$IR_{esiah}(T) = (27) \, 10^{-3} \, I_{esia}(T) \, SF_{ig} \, TE \tag{11.37}$$

where $IR_{esiah}(T)$ = lifetime cancer incidence risk (effect h) from external exposure to ground (pathway e), at soil usage location s for radionuclide i for the general population (a), for exposure over the period T (risk)

$I_{esia}(T)$ = external exposure ground concentration average for radionuclide i via at soil usage location s, for the adult age group (a) over exposure time period T (Bq/kg)

SF_{ig} = slope factor for external exposure to ground (g) of radionuclide i (risk/y per pCi/g soil)

27 = unit conversion factor (pCi/Bq)

10^{-3} = unit conversion factor (kg/g)

TE = exposure time (y)

The corresponding equation for external exposure to contaminated sediment is as follows.

$$IR_{sriah} = (27) \, 10^{-3} \, I_{sria}(T) \, SF_{ig} \, TE \tag{11.38}$$

where $IR_{sriah}(T)$ = lifetime cancer incidence risk (effect h) from external exposure to shoreline sediment (pathway s), at recreational water usage location r for radionuclide i for the general population (a), for exposure over the period T (risk)

200

$I_{sria}(T) =$ external exposure to shoreline sediment concentration time integral for radionuclide i at recreational water usage location r, for the adult age group (a) over exposure time period T (Bq h/m^2)

and other terms are as previously defined.

11.3.3 Use of Age- and Organ-Dependent Risk Factors

The supporting material for Federal Guidance Report 13 (Eckerman 1998) provides radionuclide health conversion factors for external (ground-plane, soil volume, and semi-infinite plume only) and internal (inhalation and ingestion) exposures. The risk factors are based on a hypothetical stationary U.S. population, and are provided as a function of age for internal emitters, and only for adults for external exposures. Risk factors are provided for both cancer morbidity (incidence) and mortality. For inhalation, the risk factors are provided for the lung absorption rates (F-fast, M-medium, S-slow) of ICRP Publication 66 (ICRP 1994). For ingestion, factors are provided for materials ingested with water and for materials ingested with foods. In GENII Version 2, risks are estimated with the Federal Guidance Report 13 parameters where applicable, and parallel calculations are made using the dose/risk factor approach described in Section 11.2.1 where necessary for completeness.

11.3.3.1 External Exposure Pathway Risk Assessment

Radiation risk from external exposure pathways is evaluated using the average medium concentrations, the exposure times, and the external risk coefficient appropriate to the medium where this is possible. The external risk coefficients are provided for exposure of adults in FGR 13 (EPA 1998) in terms of risk to specific organs and the total risk for an individual. The dose coefficients are presented as dose rate factors that are multiplied by the medium average concentration and exposure time to give the total radiation dose for the defined exposure period. The following equations describe estimation of the equivalent dose and effective dose from external exposure pathways.

External Exposure from Air Immersion The evaluation of risk from a plume of radioactivity may be evaluated using the finite plume model or the semi-infinite plume model. When the finite plume model is used the dose is evaluated by the atmospheric transport component because the dose is a function of plume dimensions, and a dose-to risk conversion is applied as described in Section 11.2.1. When the semi-infinite plume model is used, the atmospheric transport analysis provides the time-integral of plume concentration at the exposure locations, which is used in the analysis described here. For the semi-infinite plume model, the risk from external exposure is evaluated as follows.

$$IR_{eaigT}(T) = I_{eaig}(T) \; RC_{igaT} \; TE_a \; 3.15 \times 10^7 \qquad (11.39)$$

where $IR_{eaigT}(T)$ = risk to organ or tissue T from external exposure to radionuclide i from plume immersion at air usage location a for an individual in age group g (risk)

RC_{igaT} = risk coefficient for air immersion to an organ T, radionuclide i, for an individual in age group g (m^3 per Bq s)

TE_a = time of exposure, either T_{ex} for acute releases or T_{yr} for chronic releases (y)

$3.15x10^7$ = units correction (s/y).

External Exposure from Ground Contamination The risk from external exposure to contaminated ground is evaluated as follows.

$$IR_{esigT}(T) = I_{esig}(T) \ RC_{iggT} \ TE_g \ 3.15x10^7 \ / \rho_s \ d_s \qquad (11.40)$$

where $IR_{esigT}(T)$ = risk to organ T from external exposure to radionuclide i from plume immersion at soil usage location s for an individual in age group g for exposure over time period T (risk)

$I_{esig}(T)$ = external exposure average soil concentration for radionuclide i for plume immersion at soil usage location s for individuals in age group g for exposure over time period T (Bq/kg)

RC_{iggT} = equivalent dose coefficient to organ T for external exposure to ground for radionuclide i for an adult (m^2 per Bq s)

TE_g = time of exposure, either T_{eg} for acute releases or T_{yr} for chronic releases (y)

ρ_s = surface soil bulk density (kg/m^3)

d_s = thickness of surface soil layer (m)

$3.15x10^7$ = units correction (s/y).

External Exposure from Swimming The risk from external exposure while swimming is evaluated as follows.

$$IR_{wrigT}(T) = 10^{-3} I_{wrig}(T) \ HC_{iawT} \ HC_{gh} \ TE_w \ 3.15x10^7 \qquad (11.41)$$

where $IR_{wrigT}(T)$ = risk to organ T from external exposure to radionuclide i while swimming at recreational water usage location r for an individual in age group g for exposure over time period T (risk)

$I_{wrig}(T)$ = external exposure average water concentration for radionuclide i for swimming at recreational water usage location r for individuals in age group g for exposure over time period T (Bq/m^3)

HC_{gh} = health effects conversion factor for effect h and an individual in age group g (risk/Sv)

HC_{iawT} = equivalent dose coefficient to organ T for external exposure from water immersion for radionuclide i for an adult (Sv L per Bq s)

10^{-3} = unit conversion factor (m^3/L)

TE_w = time of exposure, either T_{ew} for acute releases or T_{yr} for chronic releases (y)

3.15×10^7 = units correction (s/y).

As indicated in these equations, the adult equivalent dose (HC_{iaaT}) and effective dose coefficients (EC_{iaa}) are used for all age groups, as represented by the subscript "a" (adult) in place of the general age group subscript "g". This is a necessary approximation because age-dependent effective dose coefficients are not available for external exposures.

External Exposure from Boating In a manner similar to the swimmming risk, the risk from external exposure while boating is evaluated as follows.

$$IR_{brigT}(T) = 10^{-3} I_{brig}(T) \ HC_{iawT} \ HC_{gh} \ TE_b \ 3.15 \times 10^7 \ / \ 2 \tag{11.42}$$

where $IH_{brigT}(T)$ = equivalent dose to organ T from external exposure to radionuclide i while boating at recreational water usage location r for an individual in age group g for exposure over time period T (Sv)

$I_{brig}(T)$ = external exposure average water concentration for radionuclide i while boating at recreational water usage location r for individuals in age group g for exposure over time period T (Bq /L)

HC_{iawT} = equivalent dose coefficient to organ T for external exposure from water immersion (w) for radionuclide i for an adult (Sv m^3 per Bq s)

HC_{gh} = health effects conversion factor for effect h and an individual in age group g (risk/Sv)

10^{-3} = unit conversion factor (m^3/L)

TE_b = time of exposure, either T_{eb} for acute releases or T_{yr} for chronic releases (y)

2 = factor to account for being at the water surface rather than immersed (dimensionless)

3.15×10^7 = units correction (s/y).

External Exposure from Shoreline Sediment The equivalent dose from external exposure to contaminated shoreline is evaluated as follows.

$$RH_{srigT}(T) = I_{srig}(T) \, RC_{iagT} \, TE_s \, 3.15 \times 10^7 / \rho_s \, d_s \qquad (11.43)$$

where $RH_{srigT}(T)$ = risk to organ T from external exposure to radionuclide i from shoreline sediment at recreational water usage location r for an individual in age group g for exposure over time period T (risk)

$I_{srig}(T)$ = external exposure average sediment concentration for radionuclide i for shoreline sediment at recreational water usage location r for individuals in age group g for exposure over time period T (Bq/kg)

RC_{iagT} = equivalent dose coefficient to organ T for external exposure to ground (the soil surface factor is used for sediment as well) for radionuclide i for an adult (m^3 per Bq s)

TE_s = time of exposure, either T_{es} for acute releases or T_{yr} for chronic releases (y)

ρ_s = surface soil bulk density (kg/m^3)

d_s = thickness of surface soil layer (m)

3.15×10^7 = units correction (s/y).

The soil external risk factor is used for the shoreline sediment exposure pathway. A shore width factor is applied in evaluation of the time-integral of shoreline sediment concentration to account for the narrow width of the shoreline (less than infinite), as described in Section 10.

11.3.3.2 Ingestion Exposure Pathway Risk Assessment

The ingestion risks are evaluated for each ingestion exposure pathway using the ingestion risk coefficients. The evaluation is similar for all ingestion pathways; the medium concentration intake parameter (e.g. $I_{csig}(T)$) is multiplied by the appropriate risk coefficient (i.e., RC_{12oc5} as defined in Table 11.3). The following equations describe calculation of radiation doses for food crops, animal products, aquatic foods, drinking water, and soil ingestion pathways.

Ingestion of Food Crops The risk from ingestion of food crops (leafy vegetables, other vegetables, fruit, and cereal grains) is evaluated as follows.

$$RH_{csigT}(T) = I_{csig}(T)\ RC_{igocT} \tag{11.44}$$

where $RH_{csigT}(T)$ = risk to organ T from ingestion intake of radionuclide i in food crop c at soil usage location s for an individual in age group g for exposure over time period T (risk)

$I_{csig}(T)$ = ingestion intake of radionuclide i in food crop c at soil location s for individuals in age group g for exposure over time period T (Bq)

RC_{igocT} = risk coefficient to organ T for food ingestion intake of radionuclide I of class c for an individual in age group g (/Bq).

Ingestion of Animal Products The risk from ingestion of animal products (beef/meat, cow's milk, poultry, and eggs) is evaluated as follows.

$$RH_{asigT}(T) = I_{asig}(T)\ RC_{igocT} \tag{11.45}$$

where $RH_{asigT}(T)$ = risk to organ T from ingestion intake of radionuclide i in animal product a at soil usage location s for an individual in age group g for exposure over time period T (risk)

$I_{asig}(T)$ = ingestion intake of radionuclide i in animal product a at soil location s for individuals in age group g for exposure over time period T (Bq)

RC_{igocT} = risk coefficient to organ T for food ingestion intake of radionuclide i of class c for an individual in age group g (/Bq).

Ingestion of Aquatic Foods The risk from ingestion of aquatic foods (fish, crustaceans, mollusks, and aquatic plants) is evaluated as follows.

$$RH_{fwigT}(T) = I_{fwig}(T)\ RC_{igocT} \tag{11.46}$$

where $RH_{fwigT}(T)$ = risk to organ T from ingestion intake of radionuclide i in aquatic food f at water usage location w for an individual in age group g for exposure over time period T (risk)

$I_{fwig}(T)$ = ingestion intake of radionuclide i in aquatic food f at water usage location w for individuals in age group g for exposure over time period T (Bq)

RC_{igocT} = risk coefficient to organ T for food ingestion intake of radionuclide i of class c for an individual in age group g (/Bq).

Ingestion of Drinking Water The risk from ingestion of drinking water is evaluated as follows.

$$RH_{dwigT}(T) = I_{dwig}(T)\ RC_{igoc\,T} \qquad (11.47)$$

where $RH_{dwigT}(T)$ = risk to organ T from ingestion intake of radionuclide i in drinking water at water usage location w for an individual in age group g for exposure over time period T (risk)

$I_{dwig}(T)$ = ingestion intake of radionuclide i in drinking water at water usage location w for individuals in age group g for exposure over time period T (Bq)

RC_{igocT} = risk coefficient to organ T for water ingestion intake of radionuclide i of class c for an individual in age group g (/Bq).

Note that the risk coefficient is specifically designated for drinking water in FGR 13.

Ingestion of Soil The equivalent dose from inadvertent ingestion of soil is evaluated as follows.

$$RH_{dsigT}(T) = I_{dsig}(T)\ RC_{igocT} \qquad (11.48)$$

where $RH_{dsigT}(T)$ = risk to organ T from ingestion intake of radionuclide i in soil at soil usage location s for an individual in age group g for exposure over time period T (Sv)

$I_{dsig}(T)$ = ingestion intake of radionuclide i in soil at soil location s for individuals in age group g for exposure over time period T (Bq)

RC_{igocT} = risk coefficient to organ T for foods ingestion intake of radionuclide I of class c for an individual in age group g (/Bq).

Inadvertent Ingestion of Water While Swimming The risk from ingestion of water while swimming is evaluated as follows.

$$RH_{w\,wigT}(T) = I_{w\,wig}(T)\ RC_{igocT} \qquad (11.49)$$

where $RH_{wwigT}(T)$ = risk to organ T from ingestion intake of radionuclide i in swimming water at water usage location w for an individual in age group g for exposure over time period T (risk)

$I_{wwig}(T)$ = ingestion intake of radionuclide i in swimming water at water usage location w for individuals in age group g for exposure over time period T (Bq)

RC_{igocT} = risk coefficient to organ T for water ingestion intake of radionuclide i of class c for an individual in age group g (/Bq).

Note that the risk coefficient is designated for drinking water in FGR 13.

Inadvertent Ingestion of Water While Showering The risk from ingestion of shower water is evaluated as follows.

$$RH_{h\,wigT}(T) = I_{h\,wig}(T)\ RC_{igoc\,T} \tag{11.50}$$

where $RH_{hwigT}(T)$ = risk to organ T from ingestion intake of radionuclide i in shower water at water usage location w for an individual in age group g for exposure over time period T (risk)

$I_{hwig}(T)$ = ingestion intake of radionuclide i in shower water at water usage location w for individuals in age group g for exposure over time period T (Bq)

RC_{igocT} = risk coefficient to organ T for water ingestion intake of radionuclide i of class c for an individual in age group g (/Bq).

Note that the risk coefficient is designated for drinking water in FGR 13.

11.3.3.3 <u>Inhalation Exposure Pathway Risk Assessment</u>

The risks are evaluated for each inhalation exposure pathway using the inhalation riskcoefficients. The evaluation is similar for all inhalation pathways; the medium concentration intake parameter (e.g. $I_{csig}(T)$) is multiplied by the appropriate risk coefficient (i.e., RC_{12rc5} as defined in Table 11.3). The following equations describe calculation of risks for inhalation of air, resuspended soil, and indoor air contaminants.

Inhalation of Air The risk from inhalation of air is evaluated as follows.

$$RH_{aaigT}(T) = I_{aaig}(T)\ RC_{igrc\,T} \tag{11.51}$$

where $RH_{aaigT}(T)$ = risk to organ T from inhalation intake of radionuclide i in air at air usage location a for an individual in age group g for exposure over time period T (risk)

$I_{aaig}(T)$ = inhalation intake of radionuclide i in air at air usage location a for individuals in age group g for exposure over time period T (Bq)

$$RC_{igrcT} = \text{risk coefficient to organ T for inhalation intake of radionuclide i of class c for an individual in age group g (/Bq).}$$

Inhalation of Resuspended Soil The risk from inhalation of resuspended soil is evaluated as follows.

$$RH_{saigT}(T) = I_{saig}(T)\, RC_{igrc\,T} \tag{11.52}$$

where $RH_{saigT}(T)$= risk to organ T from inhalation intake of radionuclide i in resuspended soil at air usage location a for an individual in age group g for exposure over time period T (risk)

$I_{saig}(T)$ = inhalation intake of radionuclide i in resuspended soil at air usage location a for individuals in age group g for exposure over time period T (Bq)

RC_{igrcT} = risk coefficient to organ T for inhalation intake of radionuclide i of class c for an individual in age group g (/Bq).

Inhalation of Indoor Air The risk from inhalation of contaminants in indoor air is evaluated as follows.

$$RH_{vwigT}(T) = I_{vwig}(T)\, RC_{igrc\,T} \tag{11.53}$$

where $RH_{vwigT}(T)$= risk to organ T from inhalation intake of radionuclide i in indoor air at location w for an individual in age group g for exposure over time period T (risk)

$I_{vwig}(T)$ = inhalation intake of radionuclide i in indoor air at location w for individuals in age group g for exposure over time period T (Bq)

RC_{igrcT} = risk coefficient to organ T for inhalation intake of radionuclide i of class c for an individual in age group g (/Bq).

APPENDIX A

APPENDIX A: PRIMARY DATA COMMUNICATION FILES

This appendix provides details of content and structure of each of the primary communication interface files used by the GENII-V2 software package. These files are be generated by specific components of GENII-V2, or by external programs run to interface with GENII-V2. The general structure of the primary data communication files is described first, followed by detailed information for each file. The file specifications provided here are requirements of the FRAMES software package.

Primary data communication files (PDCFs) are communication interfaces between calculational components operating under the FRAMES system. The content of these files is related to radionuclide transfer rates, amounts, concentrations, intakes, or doses for particular points in the risk assessment. The content of each PDCF is dependent on the components the write and read the file. There are currently eight PDCFs defined for the GENII-V2 software package. A summary description of each is given in Table A.1, with details of each given in the following subsections. Standard file extensions are defined for each PDCF type.

Table A.1 Summary Description of PDCFs

Components Involved		File Extension	Description
Writing File	Reading File		
Source	Atmospheric Transport	AFF	Atmospheric flux file: release rates of radionuclides to the atmosphere at the source
Source	Surface Water Transport	WFF	Water flux file: release rates of radionucldies to surface water at the source
Source	Near-field Exposure	SCF	Soil concentration file: initial concentration of radionuclides in soil (surface soil, deep soil, or waste package)
Atmospheric Transport	Acute and Chronic Exposure	ATO	Air concentration file: air concentration, deposition rates, and external exposure rates to airborne radionuclides, at specific points in the environment
Surface Water Transport	Acute and Chronic Exposure	WCF	Water concentration file: concentration of radionuclides in surface water at exposure location
Exposure (acute, chronic, and near-field)	Receptor Intake	EPF	Exposure pathway file: concentration of radonuclides in exposure media
Receptor Intake	Health Impacts	RIF	Receptor intake file: estimated intakes for the exposed individual
Health Impacts	Report Generator	HIF	Health impacts file: health impact results

A.1 GENERAL STRUCTURE OF PDCFS

Each PDCF has a unique structure, defined for transmission of information between two specific components of the system. Because the PDCFs are to be used by any calculational component (not just the GENII-V2 components) to be included under the control of the Framework UI, it is necessary that the PDCF structure be compatible with many programming languages (e.g., C++ and FORTRAN). The structure of each PDCF is outlined in the following sections. These structures are subject to change as experience is gained in attempts to implement the methodology.

A general feature of each PDCF is a heading area that is defined by each module/code developer. Information included here is variable (or nothing), however, the GENII-V2 components provide an indication of the module and transport pathways included in the analysis, as well as the date and time of the generation of the file.

As with the global input data file (GID), the information in the PDCF is contained in data sets, with one set for each calculation defined for the analysis. The first line for each set contains the name of the data set and the number of lines of information that follow in the set. This line is referred to as the "marker" line.

The first line of the data set (following the marker line) for a component gives the number of lines of heading information that follow. The data for the file starts in the line after the last line of heading information. The heading information may be read (or skipped) and then the data section is read.

Within each PDCF structure, substructures are defined for definition of particular types of information. A minimum of one substructure is defined for each PDCF type. As an example of substructures, consider the "atmospheric transport medium" PDCF (defined below). This file provides information on the concentration in air and deposition rate to soil. Cases involving acute releases may be expected to require some information different than cases involving chronic exposures. Substructures to the PDCF are defined for acute and chronic exposures. A standard parameter identifier (e.g. "acute" or "chronic") at the start of a substructure defines the type of substructure present.

A.1.2 PDCF Character and Numeric Syntax

To ensure file data readability by several programming languages, the following primary standards are used for PDCFs.

· The files are visually readable (ASCII/Text).

· The files are readable by major programming languages (FORTRAN, C, Basic).

· The line syntax is compatible with FORTRAN free-field read conventions.

·   Each data value (string, integer, or float) is separated by a comma (,). Character fields are fully contained within quote (') or double quote (") marks.

·   Floating point numbers are entered as integers, floating point values, or in scientific notation.

When PDCF files are generated by FORTRAN programs, the character fields are printed using format statements (rather that the * free-field format specification). Use of a free-field write will not properly handle character strings that have embedded commas or blanks. Quote marks and commas can easily be inserted in output lines following each parameter value (string, integer, or float), as appropriate.

A.1.3 PDCF Primary Interface Parameters

Each PDCF file contains information specific to the interface components involved. Some general information will always be included, such as radionuclide names and media locations. Each PDCF will also have information specific to the interface considered. The specific information is defined in Table A.2.

A.1.4 Error file (ERR)

An error message file (extension ERR) is to be opened by each component. If the file has not been used by the end of the run (i.e., no error messages were generated), then the file is deleted. The Framework UI will look for the file, and if present, warn the user of possible problems with the execution of that component. All executables will create the ERR file before processing is started and delete it only after all processing is complete. The file contains text information describing errors encountered during the run. The contents of the file are displayed to the user by the Framework UI.

A.2 SOIL CONTAMINATION PDCF (SCF)

The soil concentration file (SCF) provides information on initial radioactive contamination and gives amounts in the environmental media for subsequent exposure of individuals. The contents of the file include the following general information.

·   Description of source configuration (contaminated soil, landfill, etc.)

·   Radionuclide inventory

·   Release (amount or rate) of each radionuclide and decay product in soil with timing of release as appropriate for the scenario

213

The concentration is a spatial average throughout the volume of the source zone. The concentrations are in pCi/Kg or g/Kg in vadose zone depending on whether the constituent is a radionuclide or chemical. These concentration values are the instantaneous values at that time not an average. There are no limits on number of constituents, progeny, or layers. The content and structure of the source term file is indicated in Exhibit A.1.

Table A.2. PDCF Interface Parameters

Component	File	Interface Parameters
Source Definition	SCF WFF AFF	Release rate to a transport medium, time history. Example, Bq/sec to surface water, time pairs
Transport to Transport Medium	WCF ATO	Medium concentration, time history. Example, Bq/L in groundwater, time pairs
Transport Medium to Exposure Medium	EPF	Exposure medium concentration, time history. Example, Bq/kg in vegetables grown using contaminated irrigation groundwater, over specified time periods
Exposure Medium to Intake	RIF	Exposed Human/Biota intake or exposure as appropriate to each exposure route and pathway. Examples, Bq intake from drinking water ingestion, or radiation dose Sv over the exposure duration.
Intake to Impacts	HIF	Endpoint parameter values appropriate to pollutant and exposure pathway. Examples, lifetime cancer incidence from inhalation of a radionuclide, or radiation dose (Sv effective dose) from ingestion or inhalation exposures. These endpoint are for exposure of an individual.

A.4 ATMOSPHERIC RELEASE PDCF (AFF)

The air flux file (AFF) is a spatial average through an exit area into unconstrained air passing by the area. The exit area is normally defined by physical characteristics of the source. In all cases, the exit area is the area used to define the spatial average of the air flux. The air fluxes are in pCi/yr or g/yr depending on whether the constituent is a radionuclide or chemical. These flux values are the instantaneous values at a specified time (i.e. the value is not a time-average). There are no limits on number of constituents, progeny, fluxes. The number of contaminant types is unlimited. The structure and content of the AFF files is shown in Exhibit A.3.

A.6 EXPOSURE PATHWAY TO RECEPTOR INTAKE FILE (.EPF)

The exposure medium component reads files providing transport medium concentrations and determines concentrations in media to which the individuals or population are exposed. The output from the exposure medium component is the concentration of each constituent in the media of interest. For external exposure pathways the output is either radiation dose (finite plume model) or time integral of medium concentration. This is the input to the intake assessment component (which produces estimates of intake and external exposure). The file extension is .EPF (exposure pathway file). Following the header information, intake information is provided for all receptor locations, exposure pathways, and constituents. The content and structure of the EPF file is indicated in Exhibit A.6.

Concentration units are Bq/unit medium for radionuclides. For finite plume external exposure, dose units are used, Sv. The medium concentration units are: air - m^3, soil - kg or m^2, water - L, foods - kg.

A.7 RECEPTOR INTAKE FILE (.RIF)

The output from the receptor intake component is the intake amount for each constituent for each receptor exposure pathway. This is the input to the health impacts component (which produces estimates of health impacts, e.g., risk of developing cancer, hazard quotient, radiation dose, etc.). The input to the health impacts component is provided in this Primary Data Communication File, extension RIF (Receptor Intake File). This file provides intake amounts for each age group (as specified by the user). Following the header information, intake information is provided for all receptor locations, exposure pathways, and constituents. The content and structure of the RIF file is indicated in Exhibit A.7.

Intake units are Bq for radionuclides. For external finite plume exposure, dose units are used, Sv. The number of values is equal to the number of age groups defined for the current data set.

A.8 HEALTH IMPACTS TO OUTPUT REPORTS (.HIF)

The output from the Health Impacts Component is used by the report generators to prepare text reports. This file has an extension of HIF (health impacts file). The health impacts are expressed as the risk of developing cancer, either as total incidence, fatal incidence, or incidence of severe genetic effects, depending on the method used to evaluate health impacts (see Section 11). The input to the impacts report generator component is provided in the Primary Data Communication File, extension .HIF. Following the header information, data is provided for all receptor locations, exposure pathways, constituents, and health endpoints. The content and structure of the HIF file is indicated in Exhibit A.8.

One health impact measure value is given for each age group. Health impact units are "Risk" for carcinogenic effects, "HQ" for hazard quotient values for non-carcinogenic effects, and "Sv" for radiation dose.

APPENDIX B

APPENDIX B: AUXILIARY DATA COMMUNICATION FILES

This appendix provides detailed descriptions of content and structure of the auxiliary data communication files used by GENII-V2 modules.

B.1 Radionuclide Master Data File Content

The radionuclide master data library (RMDLIB.DAT) contains all radiological decay data in addition to the specification of all radionuclides for which data is included in the GENII-V2 software system. The radionuclides are organized into decay chains ordered by atomic number under the radionuclides highest in the chain. The data in this file are used by the chain decay processor to account for radioactive decay and progeny ingrowth with time. RMDLIB.DAT currently contains information on 825 radionuclides.

Each parent radionuclide entry has at least 2 lines of data. If the radionuclide is the head of a decay chain, then there will be as many additional entries as there are additional members of the decay chain, one line per progeny. In some instances (primarily where the decay progeny has a very short half-life with respect to the parent), progeny are included "implicitly" – their decay energy is included with that of the parent in all applications. In these cases, the implicit progeny are included in the chain, but without indication of half-life.

The first line of the file is descriptive information. The second line indicates detail about the structure of the following data: the maximum number of explicit decay progeny in a chain and the maximum number of implicit progeny in any one chain. The remaining records are set up in blocks for each parent radionuclide. This structure allows consideration of chain decay progeny and released progeny separately in the GENII-V2 calculations. The structure of the data blocks is given in Table B.1.

B.2 External Radiation Dosimetry Conversion Factor Files

The files F12TIII1.EXT, FGR12F32.DAT, F12TIII3.EXT, and F12TIII7.EXT contain dose rate conversion factors derived from Federal Guidance Report 12 for exposure to immersion in air, immersion in water, soil surface, and soil volume contamination, respectively. Each contains information for 825 radionuclides, and for each factors for 25 organs or tissues in the body.

The files contain three lines of header information, and 828 lines of data, as illustrated in Table B.2. The file format is A7, 25E9.2. The units vary between the four files. For the air submersion , water immersion, and soil volume files, the units are Sv/s per Bq/m^3. For the soil surface contamination file, the units are Sv/s per Bq/m^2.

TABLE B.1. Radionuclide Master Library Record Structure

Field Number	Data Type	Field Size	Description
Record 1:			
1	CHARACTER	8	Radionuclide identifier
2	INTEGER	5	Number of explicit members in the chain
3	INTEGER	5	Number of implicit members in the chain
Record 2:			
1	CHARACTER	8	Radionuclide identifier (all caps)
2	REAL	13	Half-life (days)
3	INTEGER	2	Chain position number
4	INTEGER	2	Position of first parent
5	REAL	7	Branching ratio from first parent
6	INTEGER	2	Position of second parent
7	REAL	7	Branching ratio from second parent
8	INTEGER	4	Atomic mass number
9	CHARACTER	2	Bone seeker classification (not used by GENII-V2)
10	CHARACTER	1	ICRP-30 Primary lung class (not used by GENII-V2)

TABLE B.2. External Dose Conversion Factor File Record Format

Field Number	Data Type	Field Size	Description
1	CHARACTER	7	Alphabetical symbol as specified in the master radionuclide library
2-26	REAL	9	Organ-specific dose rate conversion factor.

B.3 Ingestion Radiation Dosimetry Conversion Factor Files

   The dose conversion factors for ingestion calculated using the latest ICRP methods are provided in the file FGR13ING.GDB. This file includes significantly more data than are currently being used in GENII-V2. The file provides age-dependent radiation doses for radionuclides for various values of the gut-to-blood transfer factor (f1). The ages for which data are specified are 100 days, 1 year, 5 years, 10 years, 15 years, and 20 years. Data are provided for 33 organs, tissues, or lung compartments in the ICRP models. This information was provided by Dr. K.F. Eckerman of Oak Ridge National Laboratory.

   The file contains two lines of header information, followed by blocks of data for each radionuclide. For some radionuclides, information is provided for both low-LET and high-LET radiations; these radionuclides have 2 lines of data as indicated in the fourth field. The format of the information is provided in Table B.3.

TABLE B.3. Ingestion Dose Conversion Factor Library Record Format

Field Number	Data Type	Field Size	Description
1	CHARACTER	7	Alphanumeric symbol as specified in the master radionuclide library
2	INTEGER	5	Age for which data on this line are applicable, days
3	REAL	8	Gut-to-blood transfer fraction (f1), dimensionless
4	INTEGER	2	Number of lines of data (1 or 2)
5-37	REAL	10	Organ/tissue dose factor, Sv/Bq

B.4 Inhalation Radiation Dosimetry Conversion Factor Files

   The dose conversion factors for inhalation calculated using the latest ICRP methods are provided in the file FGR13INH.GDB. The file provides age-depended radiation doses for radionuclides for an inhaled particle size of one micrometer, ICRP lung transfer classes (Fast, Medium, or Slow), and gut-to-blood transfer factor (f1). The ages for which data are specified are 100 days, 1 year, 5 years, 10 years, 15 years, and 20 years. Data are provided for 33 organs, tissues, or lung compartments in the ICRP models. This information was provided by Dr. K.F. Eckerman of Oak Ridge National Laboratory.

   The file contains two lines of header information, followed by blocks of data for each radionuclide. For some radionuclides, information is provided for both low-LET and high-LET radiations; these radionuclides have 2 lines of data as indicated in the seventh field. The format of the information is provided in Table B.4.

TABLE B.4. Inhalation Dose Conversion Factor Library Record Format

Field Number	Data Type	Field Size	Description
1	CHARACTER	7	Alphanumeric symbol as specified in the master radionuclide library
2	INTEGER	5	Age for which data on this line are applicable, days
3	REAL	5	Particle size aerodynamic median activity diameter, micometers
4	CHARACTER	2	ICRP lung transfer class, F, M, or S
5	CHARACTER	2	Flag for Equivalent dose or Absorbed dose, unused
6	REAL	8	Gut-to-blood transfer fraction (f1), dimensionless
7	INTEGER	2	Number of lines of data (1 or 2)
8-40	REAL	10	Organ/tissue dose factor, Sv/Bq

B.5 External Radiation Risk Conversion Files

The file FGR13EXT.RBS provides the risk factors for external exposure for the pathways of air submersion, soil ground plane, and soil volume sources. Data are provided for 15 cancer sites for 5 age groups. These age groups differ from those for the dose conversion factors; they are 0-5 years, 5-15, 15-25, 25-70, and lifetime. This information was provided by Dr. K.F. Eckerman of Oak Ridge National Laboratory.

The file contains 3 header lines to identify and organize the material, followed by three blocks of data for each radionuclide. The format of the information is provided in Table B.5.

TABLE B.5. External Risk Conversion Factor Library Record Format

Field Number	Data Type	Field Size	Description
1	CHARACTER	7	Alphanumeric symbol as specified in the master radionuclide library
2	CHARACTER	11	Mode descriptor (air, soil surface, or soil volume)
3	CHARACTER	10	Cancer site descriptor for this line
4-8	REAL	9	Risk of mortality conversion factor for the five age groups, risk per Bq-s
9-13	REAL	9	Risk of morbidity conversion factor for the five age groups, risk per Bq-s
14	CHARACTER	22	Descriptor of source file for ORNL data
15	CHARACTER	10	Date of generation of data

B.6 Ingestion Radiation Risk Conversion Files

The file FGR13ING.RBS provides the risk factors for ingestion exposure.   Data are provided for two intake pathways – drinking water and food. Information is provided on the f1 values used, but only one selection is currently available in this file for each radionuclide. Data are provided for 15 cancer sites for 5 age groups. These age groups differ from those for the dose conversion factors; they are 0-5 years, 5-15, 15-25, 25-70, and lifetime. This information was provided by Dr. K.F. Eckerman of Oak Ridge National Laboratory.

The file contains 3 header lines to identify and organize the material, followed by two blocks of data for each radionuclide. The format of the information is provided in Table B.6.

TABLE B.6. Ingestion Risk Conversion Factor Library Record Format

Field Number	Data Type	Field Size	Description
1	CHARACTER	7	Alphanumeric symbol as specified in the master radionuclide library
2	CHARACTER	11	Mode descriptor (Drinking water or dietary)
3	REAL	8	Gut-to-blood transfer (f1)
4	CHARACTER	10	Cancer site descriptor for this line
5-9	REAL	9	Risk of mortality conversion factor for the five age groups, risk per Bq
10-14	REAL	9	Risk of morbidity conversion factor for the five age groups, risk per Bq

B.7 Inhalation Radiation Risk Conversion Files

The file FGR13INH.RBS provides the risk factors for inhalation exposure.   Data are provided for two intake pathways – drinking water and food. Information is provided on the f1 values used, but only one selection is currently available in this file for each radionuclide. Data are provided for 15 cancer sites for 5 age groups. These age groups differ from those for the dose conversion factors; they are 0-5 years, 5-15, 15-25, 25-70, and lifetime. This information was provided by Dr. K.F. Eckerman of Oak Ridge National Laboratory.

The file contains 3 header lines to identify and organize the material, followed by two blocks of data for each radionuclide. The format of the information is provided in Table B.7.

TABLE B.7. Inhalation Risk Conversion Factor Library Record Format

Field Number	Data Type	Field Size	Description
1	CHARACTER	7	Alphanumeric symbol as specified in the master radionuclide library
2	REAL	5	Particle size, currently limited to 1 micrometer AMAD
3	CHARACTER	2	ICRP lung transfer class, F, M, or S
4	CHARACTER	2	Flag for Equivalent dose or Absorbed dose, unused
5	REAL	8	Gut-to-blood transfer (f1)
6	CHARACTER	10	Cancer site descriptor for this line
7-11	REAL	9	Risk of mortality conversion factor for the five age groups, risk per Bq
12-16	REAL	9	Risk of morbidity conversion factor for the five age groups, risk per Bq

B.8 Dose and Risk Factor Index File

The files described in Sections B.2 through B.7 are used in the GENII-V2 codes as direct access files. Thus, each radionuclide requires an individual address within each file. This address is provided in the file FGR13CD.NDX. This file, provided by Oak Ridge National Laboratory, contains additional information unused by the GENII-V2 codes. This file is necessary for the file-reading routines to access the available data quickly.

B.9 Atmospheric Cloud Shine Dose Rate Factor File

The GENII-V2 atmospheric transport modules use a separate file of dose rate factors for infinite lines and planes. The data are derived from the larger dose rate factor files described in Section B.2, but are provided for a fixed range of distances. Buildup and shielding by the atmosphere are included. The first line is a listing of distances in meters for which the following data apply. Each radionuclide has a three-line entry. The format of these entries is shown in Table B.8

Table B.8 Atmospheric Plume Dose Rate Factor File Record Format

Field Number	Data Type	Field Size	Description
Record 1			
1	CHARACTER	10	Alphanumeric radionuclide symbol
2	INTEGER	2	Typing identifier (particle, noble gas, reactive gas) (Not used by GENII-V2
3-23	REAL	11	Infinite line source dose rate factor
Record 2			
1-20	REAL	11	Infinite plane source dose rate factor
Record 3			
1	REAL	11	Infinite plane source factor (Sv per Ci s/m^2)
2	REAL	11	Infinite plume source factor (Sv per Ci s/m^3)

B.10 FRAMES Connection Files

The GENII system works within the FRAMES framework. This requires a large number of "Description" files (*.DES files). These files describe the interconnected relationships of the GENII-V2 system to FRAMES.

TABLE B.9. Pseudo-code Description of DES File Contents

Line with: Modeling framework check-"mf"

       - Reference to validation documents if they exist
       - Hardware requirements
       - Contact point for question regarding the model

APPENDIX C

APPENDIX C: RADIOLOGICAL CHAIN-DECAY PROCESSOR

A general solution to first-order compartmental models is presented in this appendix for application to systems consisting of one physical medium that contains any number of radionuclide decay chain members. The solution can be applied to any such system involving physical transfers from the medium and radioactive chain decay with branching. The general analytical solution to the problem is described mathematically and extended to evaluation of the time integral of the radionuclide quantities and to cases involving deposition from outside sources. For deposition at a constant rate during a time period, the general solution can be applied to determine the quantity present during the time period and the time integral of the quantity during the time period.

Various methods have been described for evaluating systems involving radioactive decay (Bateman 1910; Friedlander and Kennedy 1955; Hamawi 1971; Scherpelz and Desrosiers 1980) and physical transfers between media (Gear 1971; Skrable et al. 1974; Hindmarsh 1983; Birchall and James 1989; Kirchner 1990). Some of these methods involve simple analytical solutions, such as the Bateman (1910) representation of the radioactive decay process without branching; others involve advanced numerical methods to solve multi-compartment systems such as the numerical differential equation solvers of Gear (1971) and Hindmarsh (1983) and the numerical matrix method described by Birchall and James (1989). The analytical solutions presented by Bateman (1910), Scherpelz and Desrosiers (1980), and Skrable et al. (1974) do not consider branching, but can account for branching by performing multiple applications of the equations to each possible decay path and summing the results appropriately, a method suggested by Friedlander and Kennedy (1955). The general solution presented in this paper includes chain decay with branching explicitly in the equations (Kennedy and Strenge 1992).

The general radioactive-decay-chain problem is illustrated in Figure 1. In this figure each box represents a radionuclide decay chain member in a medium. Two types of transfers may be represented: radioactive decay between chain members and physical transfer from the medium. Radioactive transitions in this system are represented as flowing from upper boxes to lower boxes; any upper box may contribute material to any lower box. Because radioactive transitions within decay chains are irreversible, upward transfers, representing recycling of material, are not considered. Physical transfers out of the medium are indicated by the downward arrows from each box.
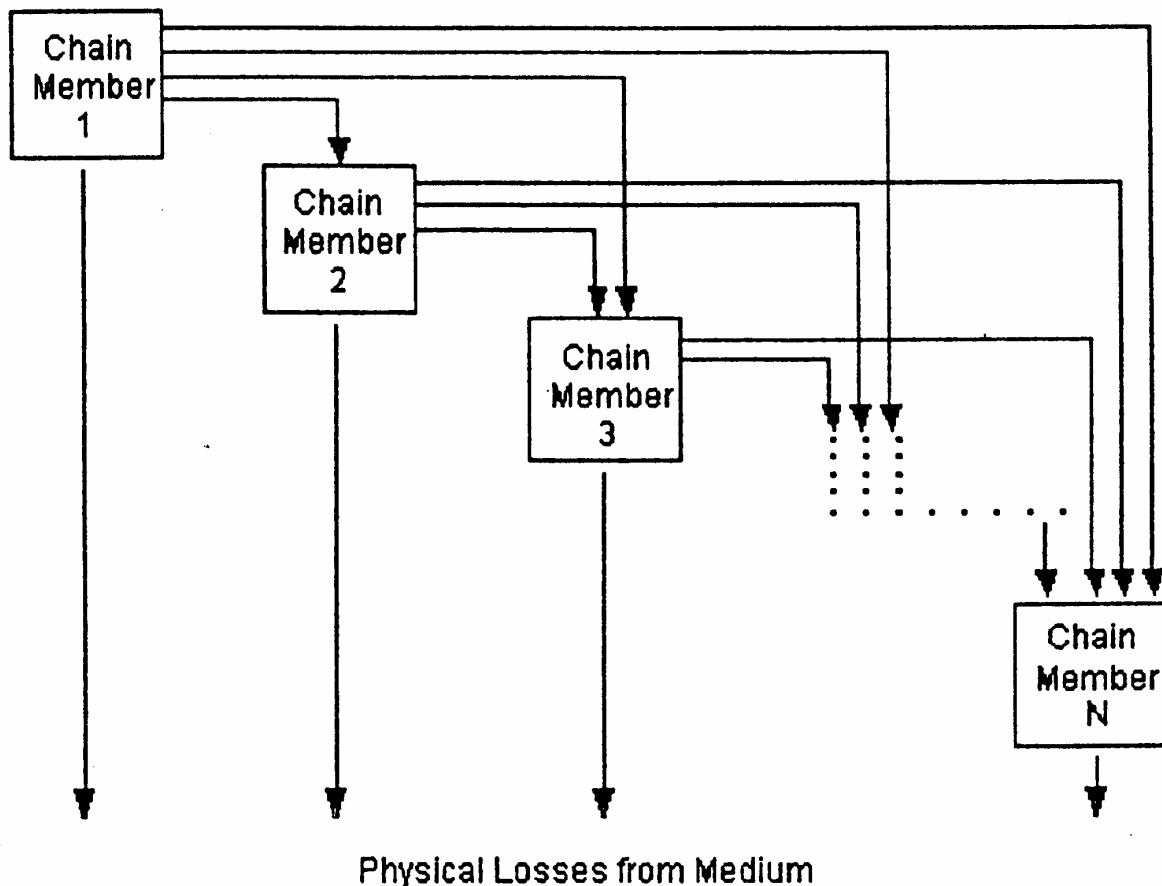

Figure C.1. A Representation of the General Radioactive-Decay-Chain Problem

Four applications are included of the general solution for the compartmental system of Figure C.1. First, the solution is presented for the evaluation of the quantity of radionuclides in each box as a function of time, based on a user-defined initial inventory. The general solution is presented for quantities expressed in units of atoms and activity. The solution then is extended for use to evaluate three additional situations. The first extension covers the evaluation of the time integral of the quantity in each box during a time period. The general solution also is shown to apply to cases involving deposition of radionuclides at a constant rate to a medium when the initial quantity in each box is zero. This application provides the quantity in each box after accumulation during a time period, and can be extended to provide the time integral of the quantity of each chain member from deposition accumulation during a time period.

General Solution

An algorithm for evaluations using the general solution equations is given to demonstrate translation of the method to computer applications. In the system of boxes as shown in Figure C.1, each box may involve 1) transfer to any other box lower in the system and 2) loss by radioactive decay within each box with generation of progeny in a lower box. Transfers between

boxes are described by rate constants. The general differential equation for the change in the quantity of a radionuclide in the medium is described by the following word equation:

(Rate of change of chain member c) =
 - (rate of physical transfer of chain member c out of the medium)
 - (rate of radioactive-transition loss of chain member c)
 + (rate of radioactive-transition ingrowth of chain member c).

Radioactive transitions of precursor radionuclides are represented in the last term.

The equivalent mathematical form of this equation is

$$\frac{d\,A_c(t)}{dt} = -L_c\,A_c(t) - \lambda_{rc}\,A_c(t) + \sum_{n=1}^{c-1} d_{nc}\,\lambda_{rn}\,A_n(t) \qquad (C.1)$$

where L_c = total rate constant for all physical transfers of chain member from the medium (d^{-1})

$A_c(t)$ = quantity of chain member c at time t (atoms)

λ_{rc} = radioactive transition rate constant for chain member c (d^{-1})

$A_n(t)$ = quantity of chain member n at time t (atoms)

d_{nc} = fraction of precursor radionuclide transitions (chain member n) that result in production of the chain member c (dimensionless)

λ_{rn} = radioactive transition rate constant for chain member n (d^{-1}).

To simplify the solution, the first two terms on the right side of Equation (C.1) can be combined as follows:

$$-L_c\,A_c(t) - \lambda_{rc}\,A_c(t) = -\lambda_{ec}\,A_c(t)$$

where λ_{ec} = effective loss rate constant for radionuclide c from the medium (d^{-1})

$$\lambda_{ec} = L_c + \lambda_{rc}$$

and other terms are as previously defined.

The first term on the right side of Equation (C.1) represents physical transfers of chain member c out of the medium. The rate constant, L_c, is the sum of all physical transfer rate constants from the media (for chain member c). The second term represents loss by radioactive transitions of the radionuclide of chain member c to progeny radionuclides in other boxes. The last term represents production of the chain member c from all precursor radionuclides.

The general solution can be summarized by the following four equations:

$$A_c(t) = \sum_{i=1}^{c} K_{ci}\, e^{-\lambda_{ei}t} \tag{C.2}$$

$$K_{11} = A_1(0) \tag{C.3}$$

$$K_{cn}(n = 1 \rightarrow c-1) = \frac{\displaystyle\sum_{i=n}^{c-1} d_{ic}\, \lambda_{ri}\, K_{in}}{\lambda_{ec} - \lambda_{en}} \tag{C.4}$$

and

$$K_{cc} = A_c(0) - \sum_{n=1}^{c-1} K_{cn} \tag{C.5}$$

The previous discussion and equations describe quantities of radionuclides expressed in units of atoms. Equations (C.2) through (C.5) can be easily converted to units of activity, such as Bq or Ci, using the general relationship between atom and activity units:

$$Q_c(t) = k\, A_c(t)\, \lambda_{rc} \tag{C.6}$$

where $Q_c(t)$ = activity of chain member c at time t (activity units)

      k = constant of proportionality between activity units and atoms (activity·time/atom)

      λ_{rc} = radioactive-transition rate constant (inverse time)

and $A_c(t)$ is as previously defined. When activity is expressed in Bq and time in seconds, the constant equals 1.

Substituting the expression in Equation (C.6) into Equations (C.2) through (C.5), with the terms slightly simplified, results in the following general solution with quantities expressed in activity units:

$$Q_c(t) = \lambda_{rc} \sum_{n=1}^{c} K_{cn}\, e^{-\lambda_{en}t} \tag{C.7}$$

$$K_{11} = \frac{Q_1(0)}{\textit{l}_{r1}} \tag{C.8}$$

$$K_{cn} (n = 1 \rightarrow c - 1) = \frac{\sum_{i=n}^{c-1} d_{ic} \, \textit{l}_{ri} \, K_{in}}{\textit{l}_{ec} - \textit{l}_{en}} \tag{C.9}$$

and

$$K_{cc} = \frac{Q_c(0)}{\textit{l}_{rc}} - \sum_{n=1}^{c-1} K_{cn} \tag{C.10}$$

The forms of Equations (C.7) through (C.10) suggest some limitations on definition of numerical values for rate constants. First, all boxes must represent a radioactive material, because the radioactive-transition rate constant appears in the denominator of Equations (C.8) and (C.10). Stable elements at the end of a decay chain can be simulated as a material with a long but finite radioactive half-life. This limitation does not apply to the general solution expressed in atom units [Equations (C.2) through (C.5)] although a stable progeny will effectively terminate a radioactive decay chain, because the rate constant for a stable isotope is zero. Another limitation is that the effective rate constant for any two boxes, λ_{ec} and λ_{en}, must not be equal, because their difference appears in the denominator of Equations (C.4) and (C.9). This limitation applies only to pairs of chain members that have radioactive transfers from one to the other.

Use of the general solution given here requires definition of all rate constants and branching fractions. Data on radionuclide half-lives, decay chains, and fractional branching within chains have been published by Lederer and Shirley (1978) and the International Commission on Radiological Protection in ICRP Publication 38 (ICRP 1983).

Extension to Time-Integration

The discussions and equations to this point have centered on evaluation of the quantity of radionuclides present as a function of time. The general solution can be extended easily to provide the time integral of the quantity present during a time period. This extension is demonstrated by observing that the general solution includes the time variable, t, only in the exponential term of Equations (C.2) and (C.7). Obtaining the time-integral expression involves simply integrating the exponential expression and evaluating the integral from time zero to the desired time. The following sequence applied to Equation (C.7) illustrates these steps:

$$\int_0^t Q_i dt = \int_0^t \lambda_{ri} \left[\sum_{n=1}^i K_{in} e^{-\lambda_{en}t} \right] dt$$

$$= \lambda_{ri} \sum_{n=1}^i K_{in} \left[\int_0^t e^{-\lambda_{en}} dt \right]$$

$$= \lambda_{ri} \sum_{n=1}^i K_{in} \left[\frac{e^{-\lambda_{en}t}}{-\lambda_{en}} \right]_0^t ,$$

The general solution for the time now uses the following formula with Equations (C.8), (C.9), and (C.10):

$$\int_0^t Q_c \, dt = \boldsymbol{\mathit{l}}_{rc} \sum_{n=1}^c K_{cn} \left[\frac{1 - e^{-\boldsymbol{\mathit{l}}_{en}t}}{\boldsymbol{\mathit{l}}_{en}} \right] \qquad (C.12)$$

Extension to Deposition at a Constant Rate

Another extension of the general solution applies to deposition of radionuclides to a medium and accumulation during a time period. The extension assumes that there are initially no radionuclides in the medium. The differential equation for chain member c is based on Equation (C.1) with an added term representing the constant rate of deposition of chain member c to the medium, R_c:

$$\frac{d A_c(t)}{dt} = R_c - \boldsymbol{\mathit{l}}_{ec} A_c(t) + \sum_{n=1}^{c-1} d_{nc} \boldsymbol{\mathit{l}}_{rn} A_n(t) \qquad (C.13)$$

where R_c = constant deposition rate of chain member c to the medium (atoms/d) and other terms are as previously defined. The general solution to this problem is written as follows, with quantities expressed in activity units:

$$Q_c(t) = \boldsymbol{\mathit{l}}_{rc} \sum_{n=1}^c K_{cn} \left[\frac{1 - e^{-\boldsymbol{\mathit{l}}_{en}t}}{\boldsymbol{\mathit{l}}_{en}} \right] \qquad (C.14)$$

$$K_{11} = \frac{D_1}{\boldsymbol{\mathit{l}}_{r1}} \qquad (C.15)$$

$$K_{cn}(n = 1 \rightarrow c-1) = \frac{\sum\limits_{i=n}^{c-1} d_{ic}\, \lambda_{ri}\, K_{in}}{\lambda_{ec} - \lambda_{en}} \tag{C.16}$$

and

$$K_{cc} = \frac{D_c}{\lambda_{rc}} - \sum\limits_{n=1}^{c-1} K_{cn} \tag{C.17}$$

where D_c is the constant deposition rate of chain member c expressed in terms of activity (pCi/d), and other terms are as previously defined.

This solution is identical to that for the time-integral problem except for substitution of D_c for $Q_c(0)$, and the integral of the exponential for the exponential as illustrated in Equations (C.11) and (C.12).

Extension to Deposition with Time-Integral

The equations for deposition at a constant rate with accumulation can be integrated to give the time integral of the quantities in each box during a time period. This integration, similar to that described in Equation (C.11), works as follows:

$$A_i(t) = \sum_{n=1}^{i} K_{in} \left[\frac{1 - e^{-\lambda_{en}t}}{\lambda_{en}} \right],$$

$$K_{11} = R_1,$$

$$K_{in}(n = 1 \rightarrow i - 1) = \frac{\sum_{j=n}^{i-1} d_{ji}\, \lambda_{rj} K_{jn}}{\lambda_{ei} - \lambda_{en}},$$

(C.18)

or

$$\int_0^t Q_c\, dt = I_{rc} \sum_{n=1}^{c} \frac{K_{cn}}{I_{en}} \left[t - \frac{1 - e^{-I_{en}t}}{I_{en}} \right]$$

(C.19)

The general solution to the time integral of deposition at a constant rate with accumulation uses Equation (C.19) [in place of Equation (C.14)], and Equations (C.15), (C.16), and (C.17). These equations can be put in terms of atom units by using Equation (C.6), as illustrated earlier.

APPENDIX D

APPENDIX D: TRANSFER FACTORS

The transfer factor, also known as the concentration ratio or bioaccumulation factor, is the ratio of the concentration of an element in an organism of interest to the concentration in the source medium. The transfer factor applies to long-term, chronic exposure of plants and animals and is ideally measured at equilibrium. Transfer factors relate the concentration of an element in soil to the element's concentration in plant products and the concentration in animal feed to animal products; the fish transfer factor relates the concentration in water to the concentration in fish muscle tissue. Transfer factors are used in risk assessments to estimate the amount of radioactivity that could be present in a food crop or organism based on the calculated concentration in the source medium (i.e., soil or animal feed). By calculating the concentration in the food, the total intake can be estimated and a dose calculated as a result of the annual intake. In terms of radionuclides, the transfer factor is used to calculate how many curies per kilogram of soil are transferred to the edible dry plant product (Bq per kg). For vegetation, the units are kg soil/kg edible dry plants. For animal products, the transfer factor relates the daily intake to that of the animal product. Units for milk are Bq/L per Bq intake/d. For animal and fish meat products, transfer factors are measured in wet weight animal product: Bq/kg muscle per Bq/d intake for meat and Bq/kg muscle per Bq/L for fish.

Numerous studies have been undertaken to quantify transfer factors for specific chemical elements as a function of food type. These studies have been compiled in several publications. This document was written to compile a list of those transfer factors which best describe the commonly accepted factors, and to document the data sources by providing the original as well as the compilation references. In some cases, this listing contains values for elements that are not included in other compilations. Transfer factors for such elements were extrapolated from experimental data based on chemical similarities.

D.1 Selection of Transfer Factors

Transfer factors for this listing were generally selected from recommended values compiled by national or international organizations for use in radiological food chain transport calculations. (In some cases, where newer data were available, very recent references for specific values were preferred to compiled recommendations.) In general, the recommended values from more recent compilations were selected rather than those in older publications. The primary data sources are also cited where identified in the compilation document. In many cases, where neither a primary source of data nor a recommended value in a compilation was available, other methods were used to estimate transfer factors, as described in the following sections.

D.2 Compilations of Data Sources

A hierarchy of data sources was established to select recommended values for transfer factors. The most recent and comprehensive references were given priority. The first reference chosen was the International Atomic Energy Agency's Technical Report Series #364, *Handbook of Parameter Values for the Prediction of Radionuclide Transfer in Temperate Environments* (IAEA 1994). This document encompasses a wide variety of plant types and is the result of extensive background investigations. It is based on data compiled by the International Union of Radioecologists. The second reference given consideration was the NUREG/CR-5512, *Residual Radioactive Contamination From Decommissioning: Technical Basis for Translating*

Contamination Levels to Annual Total Effective Dose Equivalent (Kennedy and Strenge 1992) because of its large set of data and traceable references. Other references used to fill in data were the NCRP Report #123 (1996), *Screening Models for Releases of Radionuclides to Atmosphere, Surface Water, and Ground*, the library from the GENII Version 1.485 system of computer codes (Napier et al. 1988), and the series of documents by Coughtrey et al., *Radionuclide Distribution and Transport in Terrestrial and Aquatic Ecosystems, Vols. 1-6* (1983). The NCRP Report #123 was chosen because it is a generally accepted reference for a generic model. The GENII V.1.485 values have been in use for a decade to model the semi-arid environment at Hanford and are reasonably well documented. Although the methodology for the Coughtrey and Thorne values was somewhat different, resulting in high values for transfer factors, it was necessary to use their values to fill in data where no other information was available. When no referenceable documents were available, data were derived based on chemical groupings in the periodic table of the elements, as described below.

D.3 Food Types Evaluated

For this compendium of data, foods were grouped into the following types: beef, milk, poultry, eggs, fish, leafy vegetables, other (root) vegetables, fruit, and grain. When more than one food was listed for a given food type (e.g., spinach, cabbage and lettuce listed as leafy vegetable), the transfer factor for each food was weighted by the U.S. Department of Agriculture annual per capita consumption rate (USDA 1983), and a weighted average of transfer factors was reported for that food type.

Plant transfer factors from the IAEA Handbook #364, NUREG/CR-5512, GENII, and Coughtrey et al. are based on dry weight data (Bq per kg dry crop edible product)/(Bq/kg dry soil in the upper 20 cm). When data were presented on a wet weight basis, they were converted to dry weight using conversion factors found in Table D.1. All plant transfer factors presented in this report are based on dry weight. Animal products are presented on a wet weight or volume (milk) basis.

D.4 Methods Used to Estimate Transfer Factors

Experimental data are not available for all elements for all food types. Therefore, several methods were employed to estimate transfer factors for elements and food types where experimental data were lacking. In some cases, parameters from one vegetable type were applied to remaining vegetable types for the same element. In these cases, no adjustments were made for the wet/dry ratios for specific food types, due to the relatively large uncertainty inherent in applying the transfer factor from one food type to another. In other cases, chemical similarities among elements were the basis for estimating the transfer factor. If two or more transfer factors were available for elements in a chemical group, the geometric mean was calculated from the chemical group for the given food type (Figure 1). Where data were available for only one element in a chemical group, the transfer factor for that element was applied to other elements in the same chemical group. Specific cases are listed in the Estimated Transfer Factors section below. For the actinides, many of the values from americium were applied to other elements for which parameters were not available. Cerium was selected as the surrogate element for other lanthanides for which values were not known.

Table D.1. Dry-to-Wet-Weight Conversion Factors for Food Products [a]

Plant Type		Conversion Factor
Leafy vegetation		0.2
Other vegetables		0.25
Fruit		0.18
Grain		0.91
Beef	Forage	0.22
	Stored hay	0.22
	Stored grain	0.91
Poultry	Forage	0.22
	Stored hay	0.22
	Stored grain	0.91
Dairy	Forage	0.22
	Stored hay	0.22
	Stored grain	0.91
Eggs	Forage	0.22
	Stored hay	0.22
	Stored grain	0.91

[a] From Kennedy and Strenge (1992)

Tables D.2-D.10 list (a) the recommended transfer factors by food or crop type, (b) the compilation from which the value was taken, and (c) the original sources of data as cited in each compilation document. The following paragraphs describe how transfer factors were estimated for special cases without direct primary references.

D.5 Special Cases Without Primary References

Fish

Most of the water-to-fish transfer factors were available from one of the compilations. However, values for all lanthanides were based on Ce.

Beef

The Ta transfer factor for feed-to-beef was set equal to the Nb value, and all lanthanides were based on Ce. Unknown actinides, Ac, Pa, and Cf values were set equal to Am values for their respective food types. All other values were based on the recommended values in a compilation document.

Figure D.1. Chemical Periodic Table With Groups and Periods

Milk

The Ta, Hf, and Cf transfer factors for feed-to-milk were set equal to the values from Nb, Zr, and Am respectively. All the lanthanides were based on Ce values. All other values were based on the recommended values in a compilation document.

Poultry

The N, F, S, K, Re, Os, Au, Bi, and Po transfer factors for feed-to-poultry were derived from the geometric mean of the other available transfer factors in their respective groups. The Cr, Rh, Ta, W, and Ir poultry transfer factors were set equal to a single established value in their respective chemical groups. The transfer factors for Ga, In, Tl and Si, Sn, and Pb were based on the greatest value (most conservative) of the next periodic table group (VA) of elements. For poultry, this resulted in a value of 0.8 being assigned to the missing values. All the lanthanide elements were assigned the value for Ce. Those actinides without a value were assigned the value for Am.

Egg

The N, F, S, Cl, Sc, As, Re, Os, Hg, Bi, Po, and Ra transfer factors for feed-to-eggs were calculated as the geometric mean of the established transfer factors in their respective chemical groups. The Cr, Rh, Ag, Hf, Ta, W, Ir, and Au transfer factors for eggs were based on a single established value in their respective groups. The transfer factors for Ga, In, Tl and Si, Sn, and Pb were based on the greatest value (most conservative) for the next group (VA) of elements. For eggs, this resulted in a value of 1.0 being assigned to the missing values. All the lanthanide elements were assigned the value for Ce. Those actinides without a value were assigned the value for Am.

Fruit

The soil-to-fruit transfer factors for N, Os, Au, and Hg were calculated based on the geometric mean of the transfer factors in their respective groups on the periodic table. Hafnium (Hf) and Ta were assigned values equal to those for Zr and Nb, respectively. All the lanthanide elements were assigned the value for Ce.

Grain

The soil-to-grain transfer factors for Be, N, and Hg were calculated as the geometric mean of the transfer factors in their respective periodic table groups. Silver (Ag), Hf, Ta, and Au transfer factors for grain were based on the single known value in their respective chemical groups. All the lanthanide elements were assigned the value for Ce. The grain transfer factors for Ac, Pa, and Cf were based on Am.

Leafy Vegetation

The soil-to-leafy vegetation transfer factors for N, Hf, Ta, and Au were calculated as the geometric means of the transfer factors in their respective periodic table groups. All the lanthanide elements were assigned the value for Ce. Actinium (Ac), Pa, and Cf were assigned the leafy vegetable transfer factor from Am.

Root Vegetables

The soil-to-root transfer factors for N and Au were calculated as the geometric mean of the transfer factors in their respective periodic table groups. Hafnium (Hf) and Ta were based on a single established value in their respective chemical groups. The root transfer factors for Ac, Pa, and Cf were based on Am. All lanthanide elements were assigned the value for Ce.

D.6 Additional Transfer Factors used in GENII-V2

Three additional types of transfer factors are used in GENII-V2; these are all derived from the earlier GENII 1.485 (Napier et al. 1988) without current updating. These are the transfer factors for saltwater fish, fresh and salt water crustaceans, fresh and salt water molluscs, and fresh and salt water plants. These are listed in Tables D.11, D.12, D.13, and D.14. All transfer factors in these tables come from the GENII 1.485 data files. For marine species, the GENII 1.485 values in Napier et al. (1988) are largely traceable back to *A Model for the Approximate Calculation of Safe Rates of Discharge of Radioactive Wastes into Marine Environments* (Freke 1967). Specifically for freshwater environments, the parameters are ultimately traceable to *Concentration Factors of Chemical Elements in Edible Aquatic Organisms* (Thompson et al. 1972), which in turn is primarily derived from Ng's (1968) *Handbook for Estimating the Maximum Internal Dose from Radionuclides Released to the Biosphere*.

APPENDIX E

APPENDIX E: PARAMETERS AVAILABLE FOR STOCHASTIC ANALYSIS

Stochastic analysis using GENII Version 2 is controlled with the SUM³ processor. The variables available to the SUM³ processor are all of those defined in the respective Description files (*.DES) that attach the various GENII modules to the FRAMES system. The parameters currently defined for the system are listed in this Appendix.

For each of the GENII Version 2 modules, the parameters that are available through the Global Input Definition (*.GID) file are listed by name. This list originates for each module in the respective *.DES file. This identification indicates first, whether the parameter is stochastic or not; those that are not stochastic are generally control parameters for the calculations. The units are given, and a text description of each is provided. This text description is used in the SUM³ processor to help the user identify the use of each parameter.

E.1 FRAMES SOURCE-RELATED PARAMETERS

Parameter	Units	Description
one	m	Length of source
two	m	Width/Height for Vadose/Aquifer of source
three	m	Depth of source
four	m/yr	Flow rate
five	C	Exit Temperature
six	C	Ambient Temperature
ctime	yr	Time
cflux	g/yr	Contaminant Flux Rate for
density	g/cm^3	Density of gas particulates
radius	um	Radius of particles

E.2 GENII SURFACE WATER PARAMETERS

Parameter	Units	Minimum	Maximum	Description
GNSWTT	hr	0	10000	Travel time in surface water
GNSWDSCHG	m^3/s	0.1	50000	Total volumetric flow rate of river
GNSWVELOC	m/s	0.1	10	Average long-shore flow velocity
GNSWLSX	m	0.0001	5000000	Downstream distance
GNSWOSY	m	0.0001	10000	Offshore distance to water intake
GNSWDPTH	m	0.1	100	Constant river flow depth
GNSWWIDTH	m	0.1	10000	Constant river width
GNSWZDEP	m	0	100	Depth of the discharge point in the water body

E.3 GENII CHRONIC PLUME PARAMETERS

None currently available

E.4 GENII CHRONIC PUFF PARAMETERS

None currently available

E.5 GENII ACUTE PLUME PARAMETERS

Parameter	Units	Minimum	Maximum	Description
JHOUR	Julian hour	0	8760	Julian start hour

E.6 GENII ACUTE PUFF PARAMETERS

Parameter	Units	Minimum	Maximum	Description
JHOUR	Julian hour	0	8760	Julian start hour

E.7 GENII NEAR-FIELD EXPOSURE PARAMETERS

Parameter	Units	Minimum	Maximum	Description
PACKHL	yr	0	20	Waste package half life
ABSHUM	g/m^3	0	0.1	Absolute humidity, used only for tritium model
YELDBT	kg/m^2	0.1	20	Yearly vegetative yield (dry weight) for arid lands during optional buildup period
THICK	cm	0	10000	Surface soil thickness
MOISTC	fraction	0	1	Surface soil moisture content
BULKD	g/cm^3	0.5	3	Surface soil bulk density
VLEACH	cm/yr	0	500	Total infiltration rate
RESFAC	1/m	0	0.001	Resuspension factor
XMLF	g/m^3	0	5	Mass loading factor for resuspension model
AVALSL	cm	0.01	2	Depth of top soil available for resuspension
SLDN	kg/m^2	0.00001	3000	Surface soil areal density
SSLDN	kg/m^3	0.00001	3000	Surface soil density
SURCM	cm	0.00001	500	Surface soil layer thickness used for density
OVRBRD	m	0	20	Depth of soil overburden over waste
WASDEP	m	0.01	100	Thickness of buried waste layer
FRSIZ	m^2	1	10000	Source area for external dose modification factor
MANULR	fraction	0	1	Manual redistribution factor
DEPFR1	fraction	0	1	Dry deposition retention fraction to plants
LEAFRS	1/m	0	0.001	Resuspension factor from soil to plant surfaces
DPVRES	m/s	0	0.1	Deposition velocity from soil to plant surfaces
WTIM	d	0.1	100	Weathering rate constant from plants
RF1	fraction	0	1	Fraction of plants roots in surface soil
RF2	fraction	0	1	Fraction of plants roots in deep soil
BIOMAS	kg/m^2	0.1	10	Standing biomass (wet)
GRWP	day	0	365	Growing period
YELD	kg/m^2	0.001	10	Yield
TRANS	fraction	0	1	Translocation factor
DRYFAC	fraction	0.05	0.95	Dry/wet ratio
BIOMA2	kg/m^2	0.1	10	Animal feed standing biomass (wet)
CONSUM	kg/d	0.001	300	Animal feed consumption rate
STORTM	day	0	356	Storage time
DIETFR	fraction	0	1	Fraction of diet
GRWPA	day	0	365	Growing period for animal feed
YELDA	kg/m^2	0.1	10	Yield for animal feed
TRANSA	fraction	0	1	Translocation factor for animal feed
DRYFA2	fraction	0.05	0.95	Animal feed dry/wet ratio
HLDUP	day	0	365	Time from harvest to ingestion
HLDUPA	day	0	365	Time from harvest to animal feed ingestion
LEACHR	1/yr	0	100	Leach rate constant
SOILKD	ml/g	0	1000000	Soil adsorbtion coefficient

E.8 GENII CHRONIC EXPOSURE PARAMETERS

Parameter	Units	Minimum	Maximum	Description
ABSHUM	kg/m^3	0	0.1	Absolute humidity, used only for tritium model
RF1	fraction	0	1	Fraction of plants roots in surface soil
XMLF	g/m^3	0	5	Mass loading factor for resuspension model
AVALSL	cm	0.01	200	Depth of top soil available for resuspension
YELDA	kg/m^2	0.1	10	Yield for animal feed
HLDUPA	day	0	365	Time from harvest to animal ingestion
GRWPA	day	0	365	Animal feed growing period
STORTM	day	0	356	Storage time
DIETFR	fraction	0	1	Fraction of diet
YELD	kg/m^2	0.001	10	Yield
HLDUP	day	0	365	Time from harvest to ingestion
GRWP	day	0	365	Growing period
RIRRA	in/yr	0	200	Animal feed irrigation rate
IRTIMA	mon/yr	0	12	Animal feed irrigation time
RIRR	in/yr	0	200	Irrigation rate
IRTIMT	mon/yr	0	12	Irrigation time
HLDUP2	day	0	365	Time from harvest to ingestion
DWFACA	fraction	0	1	Animal water contaminated fraction
SSLDN	kg/m^3	0.00001	3000	Surface soil density
RIRRR	in/yr	0	200	Irrigation rate for residential land
IRTIMR	mon/yr	0	12	Irrigation time for residential land
HOLDDW	day	0	365	Delay time in water distribution system
RESFAC	1/m	0	0.001	Resuspension factor
WTIM	d	0.1	100	Weathering rate constant from plants
DEPFR1	fraction	0	1	Dry deposition retention fraction to plants
RAIN	mm/d	0.01	10	Average daily rain rate
ANDKRN	l/m^3	0	10	Indoor volatilization factor for radon
SEDDN	kg/m^2	0	5000	Shoreline sediment density
THICK	cm	0	10000	Surface soil thickness
MOISTC	fraction	0	1	Surface soil moisture content
BULKD	g/cm^3	0.5	3	Surface soil bulk density
VLEACH	cm/yr	0	500	Total infiltration rate
DEPFR2	fraction	0	1	Wet deposition retention fraction to plant surfaces
LEAFRS	1/m	0	0.001	Resuspension factor from soil to plant surfaces
DPVRES	m/s	0	0.1	Deposition velocity from soil to plant surfaces
SLDN	kg/m^2	0.00001	3000	Surface soil areal density
SURCM	cm	0.00001	500	Surface soil layer thickness used for density
DWATER	L/d	0.001	200	Intake rate of water
BIOMA2	kg/m^2	0.1	10	Standing animal feed biomass (wet)
CONSUM	kg/d	0.001	300	Consumption rate
BIOMAS	kg/m^2	0.1	10	Standing biomass (wet)
TRANSA	fraction	0	1	Translocation factor for animal feed
TRANS	fraction	0	1	Translocation factor
DRYFA2	fraction	0.05	0.95	Animal feed dry/wet ratio
DRYFAC	fraction	0.05	0.95	Dry/wet ratio

LEACHR	1/yr	0	100	Leach rate constant
SOILKD	ml/g	0	1000000	Soil adsorbtion coefficient

E.9 GENII ACUTE EXPOSURE PARAMETERS

Parameter	Units	Minimum	Maximum	Description
ACUTIM	yr	0	1	Duration of acute exposure
ABSHUM	kg/m^3	0	0.1	Absolute humidity, used only for tritium model
RF1	fraction	0	1	Fraction of plants roots in surface soil
XMLF	g/m^3	0	5	Mass loading factor for resuspension model
AVALSL	cm	0.01	200	Depth of top soil available for resuspension
YELDA	kg/m^2	0.1	10	Yield of animal feed
HLDUPA	day	0	365	Time from harvest to animal feed ingestion
GRWPA	day	0	365	Animal feed growing period
STORTM	day	0	356	Storage time
DIETFR	fraction	0	1	Fraction of diet
YELD	kg/m^2	0.001	10	Yield
HLDUP	day	0	365	Time from harvest to ingestion
GRWP	day	0	365	Growing period
RIRRA	in/yr	0	200	Irrigation rate for animal feed
IRTIMA	mon/yr	0	12	Irrigation time for animal feed
RIRR	in/yr	0	200	Irrigation rate
IRTIMT	mon/yr	0	12	Irrigation time
HLDUP2	day	0	365	Time from harvest to animal feed ingestion
DWFACA	fraction	0	1	Animal water contaminated fraction
SSLDN	kg/m^3	0.00001	3000	Surface soil density
RIRRR	in/yr	0	200	Irrigation rate for residential land
IRTIMR	mon/yr	0	12	Irrigation time for residential land
HOLDDW	day	0	365	Delay time in water distribution system
RESFAC	1/m	0	0.001	Resuspension factor

CONSUM	kg/d	0.001	300	Consumption rate
BIOMAS	kg/m^2	0.1	10	Standing biomass (wet)
TRANSA	fraction	0	1	Translocation factor for animal feed
TRANS	fraction	0	1	Translocation factor
DRYFA2	fraction	0.05	0.95	Animal feed dry/wet ratio
DRYFAC	fraction	0.05	0.95	Dry/wet ratio
FRACUT	fraction	0	1	Fraction of diet that is fresh forage
PROBAIR	percent	0	100	Probability level for air concentration
PROBDEP	percent	0	100	Probability level for deposition rate
PROBEXT	percent	0	100	Probability level for external dose
LEACHR	1/yr	0	100	Leach rate constant
SOILKD	ml/g	0	1000000	Soil adsorbtion coefficient

E.10 GENII RECEPTOR PARAMETERS

Parameter	Units	Minimum	Maximum	Description
UEXAIR	hr	0	24	Daily plume immersion exposure time
TEXAIR	day	0	365	Yearly plume immersion exposure time
SHIN	none	0	1	Indoor shielding factor
SHOUT	none	0	1	Outdoor shielding factor
UEXGRD	hr	0	24	Daily external ground exposure time
TEXGRD	day	0	365	Yearly external ground exposure time
FTIN	fraction	0	1	Fraction of time spent indoors
FTOUT	fraction	0	1	Fraction of time spent outdoors
EVSWIM	evt/day	0	10	Frequency of swimming event
TESWIM	hr	0	24	Duration of swimming event
TSWIM	day	0	365	Swimming days
USWIM	L/hr	0	10	Ingestion rate of water while swimming
SFBOAT	none	0	1	Shielding factor
EVBOAT	evt/day	0	10	Frequency of boating event
TEBOAT	hr	0	24	Duration of boating event
TBOAT	day	0	365	Boating days
EVSHOR	evt/day	0	10	Frequency of shoreline use
TESHOR	hr	0	24	Duration of shoreline use events
TSHOR	day	0	365	Shoreline days
SWFAC	none	0	1	Shoreline width factor
UCRP	kg/day	0	10	Crop consumption rate
TCRP	day/yr	0	365	Crop consumption period
UANM	kg/day	0	10	Animal product consumption rate
TANM	day/yr	0	365	Animal product consumption period
UAQU	kg/day	0	10	Aquatic food consumption rate
TAQU	day/yr	0	365	Fish consumption period
UDW	L/day	0	10	Drinking water ingestion rate
TDW	day/yr	0	365	Drinking water ingestion period
EVSHWR	evt/day	0	10	Freqency of showering event
TESHWR	hr	0	24	Duration of showering event
TSHWR	day	0	365	Showering days
USHIN	L/hr	0	10	Ingestion rate of water while showering
TSOIL	day	0	365	Soil contact days
USOIL	mg/day	0	15000	Inadvertent soil ingestion rate
UINH	m^3/day	0	50	Air inhalation rate
TINH	day/yr	0	365	Air inhalation period
UINHR	m^3/day	0	50	Resuspended soil inhalation rate
TINHR	day/yr	0	365	Resuspended soil inhalation period
FRINHR	fraction	0	1	Fraction of a day inhalation occurs
UINDRH	m^3/day	0	50	Indoor air inhalation rate
TINDRH	day/yr	0	365	Indoor air inhalation period
FRINDR	fraction	0	1	Fraction of a day indoor inhalation occurs
EQFRAC	fraction	0	1	Radon progeny indoor equilibrium fraction

E.11 GENII HEALTH PARAMETERS

Parameter	Units	Minimum	Maximum	Description
HECONINC	risk/Sv	0.0001	1	Cancer incidence conversion factor
HECONFAT	risk/Sv	0.0001	1	Cancer fatality conversion factor
SOILT	m	0.001	5	Thickness of contaminated soil/sediment layer
SLDN	kg/m^3	1	4	Density of contaminated soil/sediment layer

The user interface programs for GENII exposure and intake modules allow the user to select from sets of default parameter values. These are available in the Chronic, Acute, Near-Field, and Intake modules.

The menu bars provide Defaults that activate the window for selection of defaults from existing default parameter files. The files have the same format and parameter names as are used in the GID file for the component being run. The user interfaces display a list of files and descriptive titles for each, allowing the user to select the appropriate file for average individual or maximally-exposed individual parameters.

Default files generated for use with GENII components are indicated in the following table.

GENII Component	File Name	Description of Default Parameters
Chronic Exposure	GNDFLCXM.DEF GNDFLCXA.DEF	Chronic exposure maximum individual Chronic exposure average individual
Acute Exposure	GNDFLAXM.DEF GNDFLAXA.DEF	Acute exposure maximum individual Acute exposure average individual
Near-field Exposure	GNDFLNXM.DEF GNDFLNXA.DEF	Near-field exposure maximum individual Near-field exposure average individual
Intake	GNDFLINM.DEF GNDFLINA.DEF	Intake maximum individual Intake average individual

These files provide access to the provided default values that appear initially for all parameters in the user interfaces. Should the user find himself/herself frequently changing certain parameters, they are easily accessible by name in the respective default file. They may be permanently changed with any text editor.

The standard defaults for each user interface are listed in Tables F.1 through F.4. The descriptions of the parameters are the same as presented in Appendix E. Many parameters appear multiple times in the listings; these are inputs for dimensioned parameters. The series of indices 1 – 4 indicate the human crop foods leafy vegetables, other vegetables, fruits, and cereal grains. The series of indices 1 – 6 indicate products from animals via the following pathways: beef cow feed, poultry feed, milk cow feed, egg hen feed, beef cow forage, and milk cow forage. Note that for the GENII Intake Module, up to six age groups may be defined. Currently, the adult defaults are used for all age groups because it is not known *a priori* how the age structure will be established by the user.
